ARTICLE INFO

ABSTRACT

A growing literature suggests that, even in the absence of any ability to predict returns, holding options on the benchmarks or trading frequently can generate positive alpha. The ratio of alpha to its tracking error appraises a fund's performance. This paper derives the performance-maximizing strategy, which turns out to be a variant of a buy-write strategy, and the least upper bound on such performance enhancement. If common equity indices are used as benchmarks, the potential alpha generated from trading frequently can be substantial in magnitude, but it carries considerable risk. The statistical significance in estimated alpha is low, and the probability of a negative alpha is high. The performance enhancement from holding options can be significant – both economically and statistically – if the options' implied volatilities are higher than the volatilities of the benchmark returns. The performance-maximizing strategy derived in this paper is different from the strategies that switch portfolio exposure to the benchmarks. The exposure-switching strategies are not promising unless the switching is based on superior information.

1. Introduction

Since the seminal work of Jensen (1968), a growing literature questions whether a positive alpha does in fact imply a manager's ability to select assets by predicting returns.[1] A number of researchers answer the question by

pointing out, through simulation and examples, that, by investing in options, managers can generate a positive alpha relative to a benchmark even if they cannot predict returns.[2] However, up to this point the answers to the question have been ad hoc, leaving the literature unclear about the magnitude of alpha that can be achieved by trading frequently or holding derivative securities and the risk involved with the alpha enhancement strategy.

This paper delivers a theoretical answer to the question by deriving the explicit formulas for the trading strategy that maximizes alpha, controlling for the risk. This alpha-maximizing strategy is shown to be a variant of a buy-write strategy, which can be implemented by taking long positions in the benchmark assets and writing options on them. If common equity indices are used as

[1] The literature can be traced back to Dybvig and Ingersoll (1982), Grinblatt and Titman (1989) and Glosten and Jagannathan (1994).

[2] See Lo (2001), Hill, Balasubramanian, Krag, and Tierens (2006), Goetzmann, Ingersoll, Spiegel, and Welch (2007).

benchmarks and derivative securities are priced as in the Black-Scholes model, the potential alpha generated from trading frequently or holding options can be substantial, consistent with the numerical experiments reported in the literature.

Such alpha generating strategies, however, carry such a huge risk that the generated alpha is statistically insignificant and the probability of negative alpha is close to one-half. In this sense, the manager's ability to generate superior performance from trading frequently or holding derivatives is by and large difficult under the Black-Scholes model. In contrast, it is easier for him to be successful, even in the absence of superior information, when the implied volatility of derivative securities is higher than the volatility of the underlying benchmark securities. These results provide the theoretical implications on alpha of allowing a manager to trade while being evaluated with respect to a buy-and-hold portfolio of the given benchmark.

The starting point is the consideration of a set of risky securities a fund manager can trade. The manager aims and often claims to deliver superior performance. Clients, potential clients, and academics evaluate such claims based on a set of benchmark assets, which are available to the public, including the managers' clients and potential clients. The challenge is to evaluate the fund's return by asking: Could it be obtained from a portfolio of the benchmark assets? If not, what is the increment of the evaluated return relative to the return available in the benchmark space? How likely is the increment strictly positive? The increment is labeled as alpha. This measure of performance is widely implemented in practice, and financial information services report alpha for securities and funds. Some hedge funds have even included the word "alpha" as part of their names.

If the manager delivers a series of returns that are on average higher than those obtainable from the benchmark assets, the evaluator could infer that the manager can outperform the benchmark. The attribution of such outperformance to superior information, however, could be premature because managers have at least four sources of access to a larger space of payoffs than the space of the benchmarks. First, the manager can predict the returns of the benchmark assets and can choose portfolio weights to reflect his predictions. Second, the manager could trade securities with payoffs outside the benchmark space. Third, the manager can trade derivatives of the benchmark assets. Fourth, the manager can trade the benchmark assets more frequently than the evaluator observes the returns.

The last two sources give only the appearance of superior performance because they do not depend on the manager's access to superior information. The two sources are equivalent if derivative securities are redundant assets and their payoffs can be replicated by judiciously trading the underlying assets. Black and Scholes (1973) and Merton (1973) point out the equivalence between the payoff on derivatives and on such rule-based trading. Following the literature, this paper refers to rule-based trading designed to replicate a derivative payoff as delta trading.

The specific building blocks of the performance evaluation mechanism studied here are familiar. The evaluator decomposes the fund's return into two parts: the return's linear projection on the benchmarks and the incremental return orthogonal to the benchmarks. The expectation of the incremental return is alpha, representing the portion of the expected return that is not attainable by passive investment strategies in the benchmarks. The tracking error, which is the standard deviation of the incremental return, measures the uncertainty of alpha.

The resulting ratio of alpha to the tracking error is typically referred to as the appraisal ratio. A high appraisal ratio is interpreted as superior performance because it indicates a high probability of a positive return after subtracting financing costs and neutralizing the risks associated with the benchmarks. Maximizing the appraisal ratio is necessary for maximizing the Sharpe ratio, a widely used measure of fund performance. For a hedge fund, the appraisal ratio of the fund is itself the Sharpe ratio of the hedged position that neutralizes the benchmark risk. In statistical analysis of the portfolio's performance, the appraisal ratio is the asymptotic *t*-statistic of the estimated alpha.

Sharpe ratios and appraisal ratios are important in practice. Nonetheless, within a fund class, e.g., large cap long-only US equity, it is common to compare fund performance according to the funds' alpha rather than consider their appraisal ratios. This practice is reasonable when the leverage is similar across the compared funds (e.g., zero leverage in the large cap long-only US equity). This practice is less reasonable when comparing funds with different leverage or different sets of underlying assets (and therefore different benchmarks and tracking errors). Then attention naturally turns to the Sharpe ratio.

This paper derives the best appraisal ratio (and thus the best asymptotic *t*-statistic of alpha) a manager can obtain. Section 2 sets up the general problem and describes the benchmark space used by the evaluator and the payoff space accessible to the manager. The fundamental results are in Theorem 1: as the number of payoff observations becomes large, the maximal appraisal ratio is the safe return times the norm of the difference of the pricing kernels of the two spaces, and the maximal appraisal ratio is achieved by a payoff that can be described as a function of the pricing kernels. This section also discusses how constraints on the tracking error or on leverage transform an upper bound on the appraisal ratio into an upper bound on alpha.

A novelty of the paper is in its examination of a complete market with multiple benchmark assets. Section 3 gives a simple formula of the optimal appraisal ratio in terms of the moments of the benchmark assets (Theorem 2). The subsequent discussion shows that trading derivatives on the benchmark assets delivers only a small improvement of the Sharpe ratio and takes thousands of monthly observations to produce a statistically significant alpha. Alpha can, however, be substantial in magnitude and become statistically significant when less frequent observations or a larger benchmark space is considered (e.g., by including certain additional factors).

Another novelty of the paper is in its examination of the optimal trading strategies. Section 4 establishes that, in the case of a single benchmark asset, the strategy that maximizes the appraisal ratio and alpha consists of holding the benchmark and writing out-of-the money options

on it. Under the assumption that the Black-Scholes model governs option pricing, the best strategy still delivers low values of the appraisal ratio if the parameters are estimated from the equity indices (Theorem 3). These low values of the appraisal ratio are in contrast with the practical experience in which holding the Standard & Poor 500 and writing at-the-money call options on it has delivered economically and statistically significant alphas. Theorem 4 offers a reconciliation of the contradiction by showing that the optimal appraisal ratio is high if options are not redundant assets and are priced at an implied volatility that is higher than the volatilities of the benchmark assets.

Because alpha is measured by a linear projection of a managed fund's return onto benchmark space, it is natural to speculate that varying the fund's exposure to the benchmark can cause the fund's return to fall outside the linear space of the benchmarks and consequently create a positive alpha. Section 5 considers the performance of the benchmark-exposure-switching schemes. Theorem 5 shows that if the observation interval is fixed but the number of observation is large, then exposure-switching strategies deliver lower appraisal ratios than those covered in Theorem 1. Theorem 6 offers an asymptotic upper bound on the expected alpha if the time horizon is fixed but the observation interval converges to zero. Theorems 5 and 6 together demonstrate that benchmark-exposure-switching schemes can produce positive alpha, but they do not deliver the maximal alpha in Theorems 1 and 2. Especially, Theorem 6 suggests that the expected alpha generated by switching schemes deteriorates with the time horizon.

Section 6 concludes with a discussion of the past and future research in this area.
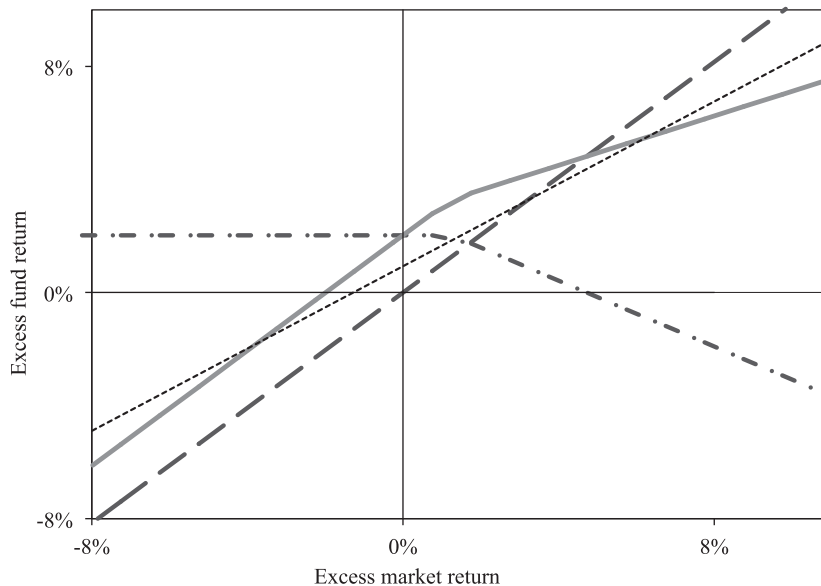

2. Performance maximization

In practice, a fund manager who is evaluated by his fund's performance relative to an index can hold the index and write options on it. (The S&P 500, Nasdaq 100, and Russell 2000 indices are examples of indices on which options can easily be written.) The intuition for the consequent payoff is illustrated in Fig. 1, which is reprinted from Wang and Zhang (2003). If the fund is fully invested in the index, the fund return (the dashed line) is a linear function of the market return with zero intercept. If the manager writes call options on the index and invests the proceeds in the safe asset, the fund return (the dotted-dashed line) is a nonlinear function of the market return. If the fund consists of a long position in the index and a short position in the options, the fund return (the thick line) has a non-zero alpha in the regression of the fund's excess return on the excess return of the index (the dotted line).

This demonstration of the possibility of generating alpha is neither an algorithm that generates the highest possible alpha nor a proof that the highest appraisal ratio can be generated in this way. Section 2.1 introduces the paper's basic framework, which to a large extent Theorem 1 captures. Theorem 1 is general, and to study special cases in later sections, further assumptions are made. Section 2.2 applies Theorem 1 to trading strategies that have been studied in the literature and shows them to be less attractive than it had been argued.

2.1. The optimization problem and its solution

The excess return r_x on an actively managed fund is evaluated against a vector of excess returns $r_m = (r_1, \ldots, r_k)'$ on k benchmark assets. The period during

Fig. 1. Generating positive alpha by writing options. A fund that is completely invested in the market index has a return equal to the market's return (the dashed line) and zero intercept. A fund that writes an index call option and invests the proceeds in the safe asset will have a return that is sensitive to the market's return in a nonlinear fashion (the dotted-dashed line). A fund that invests in the index and writes call options will also have a return that is sensitive to the market's return in a nonlinear fashion (the thick line). That return has a positive intercept in its regression on the market's return (the dotted line). Figure is reprinted from Wang and Zhang (2003).

which the fund is evaluated is from time 0 to time T. Let $\Delta t, 2\Delta t, \ldots, n\Delta t$, where $n\Delta t = T$, be the equally spaced time grid on which the evaluator observes the returns. Denote by r_{xi} and r_{mi} the observed excess returns on the fund and the benchmarks, respectively, over the time interval from $(i-1)\Delta t$ to $i\Delta t$. The regression of the excess fund returns on the excess benchmark returns is

$$r_{xi} = \alpha + r'_{mi}\beta + \varepsilon_i, \tag{1}$$

where the intercept α and the vector of slope coefficients β satisfy

$$\alpha = E[r_x - r'_m\beta] \tag{2}$$

and

$$\beta = (\text{var}(r_m))^{-1}\text{cov}(r_m, r_x). \tag{3}$$

After hedging out the risk associated with the benchmarks by adding a short position of β in the benchmark assets, the return of the hedged position is $r_x - r'_m\beta$, its expectation is α, and its tracking error is $\sqrt{\text{var}(r_x - r'_m\beta)}$. The appraisal ratio of the hedged position is its Sharpe ratio: the ratio of alpha to its tracking error. It is

$$\text{APR} = \frac{\alpha}{\sqrt{\text{var}(r_x - r'_m\beta)}}. \tag{4}$$

A high appraisal ratio indicates high profitability for the hedged position. The appraisal ratio is also the asymptotic t-statistic of alpha—the limit of the t-statistic multiplied by the square root of the number of observations in the ordinary least square (OLS) regression Eq. (1). Thus, a high appraisal ratio is associated with a high t-statistic of alpha in that regression.

The manager of the fund who seeks to maximize the appraisal ratio should have a trading strategy such that the fund return r_x solves the following maximization problem:

$$\max_x \frac{E[r_x - r'_m\beta]}{\sqrt{\text{var}(r_x - r'_m\beta)}}. \tag{5}$$

The maximization problem captures the trade-off the portfolio manager faces: To maximize the appraisal ratio, the return should have not only a high alpha but also a low tracking error (i.e., a low standard deviation of the residual return).

Before presenting the solution to the maximization problem, it is necessary to describe the payoff space and the pricing function. The space of payoffs attainable by the manager in a given period by trading in the securities available to him, denoted by X_a, is the attainable space. The payoffs are assumed to have finite second moments, that is, $X_a \subset L^2(P, \Omega)$, where Ω is a sample space and P is a probability measure, and $L^2(P, \Omega)$ is the set of all measurable functions with second moments. For any $x \in L^2(P, \Omega)$, the square root of its second moment is the norm of x, denoted by $\|x\| = E[x^2]^{1/2}$. The assumption of finite second moment is a minimal requirement to ensure that the sample estimates of linear regressions converge to their population counterparts.

The assumptions on the attainable space are standard and flexible, allowing the market to be incomplete because the space X_a is allowed to be a strict subset of

$L^2(P, \Omega)$. The dimension of X_a could be infinite. This is important because a payoff space that contains options with infinitely many strike prices and maturities has an infinite dimension. The only restriction is the linearity of the payoff space, which excludes the presence of constraints or frictions that a fund manager could face in the market.

The linear space of payoffs spanned by the benchmark assets, denoted by X_b, is the benchmark space. The number of benchmark assets is typically small, and the dimension of X_b is assumed to be $k+1$. Let $\{x_j\}_{j=0,\ldots,k}$ be the payoffs of the $k+1$ independent assets that span X_b. For simplicity and practical applications, the first benchmark payoff x_0 is assumed to be the constant payoff of a safe asset. If the payoffs in X_b do not exhaust the set of payoffs attainable by the manager, then X_b is a strict subset of X_a. A fund has abnormal return relative to the benchmarks if, and only if, its return or payoff falls outside the benchmark space.

Let $v : X_a \mapsto \Re$ be the pricing function, where $\Re$ is the set of real numbers. Assume that the law of one price holds, and thus v is linear. A stochastic discount factor for X_a is a random variable $m \in L^2(P, \Omega)$ such that $v(x) = E[xm]$ for all $x \in X_a$. Denote the set of all stochastic discount factors for X_a by M_a. By the Riesz representation theorem, some $m_a \in X_a$ exists such that $v(x) = E[xm_a]$ for all $x \in X_a$, i.e., $m_a \in X_a \cap M_a$. It follows that m_a has the smallest norm among all the stochastic discount factors in M_a (see Riesz and Sz.-Nagy, 1955, Chapter V). Because the price function also applies to the set of benchmark assets, the set of the stochastic discount factors for X_b is $M_b = \{m \in L^2(P, \Omega) : v(x) = E[mx] \text{ for all } x \in X_b\}$, and there exists a smallest norm discount factor $m_b \in X_b \cap M_b$.

A trading strategy of the fund corresponds to a payoff $x \in X_a$. To obtain excess returns, assume that the payoff of the safe asset is $x_0 = 1$ and its price is $v(1) > 0$. The return on the safe asset is $R_0 = 1/v(1)$. The excess return on the fund is $r_x = x - v(x)R_0$, and the excess return on the jth benchmark is $r_j = x_j - v(x_j)R_0$ (for $j = 1, \ldots, k$). Let $r_m = (r_1, \ldots, r_k)'$. Based on the observations of (r_x, r'_m) over n time intervals of equal length, the sample estimates of alpha (denoted by $\hat{\alpha}_n$) and appraisal ratio (denoted by $\widehat{\text{APR}}_n$) are obtained in the OLS regression Eq. (1). The sample estimate of the appraisal ratio is the t-statistic of $\hat{\alpha}_n$ multiplied by $\sqrt{n}$. As $n \to \infty$, the sample estimate converges to their population counterparts, i.e., $\lim\hat{\alpha}_n = \alpha$ and $\lim\widehat{\text{APR}}_n = \text{APR}$, where α and APR are defined in Eqs. (2) and (4), respectively. The alpha and appraisal ratio depend on the fund's strategy x and are denoted by $\alpha(x)$ and APR(x).

The optimization problem is to find a strategy $x \in X_a$ that maximizes APR(x). The maximal appraisal ratio is denoted by

$$\text{APR}_{\max} = \max\{\text{APR}(x) : x \in X_a\}. \tag{6}$$

The solution to the optimization problem equation (6) is similar in spirit to the construction of the mean–variance frontier in Hansen and Richard (1987) and Huberman and Kandel (1987), starting with the observation that any payoff can be decomposed into three components with uncorrelated payoffs. The first component accounts for beta and is alpha-neutral; the second

one accounts for alpha and is beta-neutral; the third component is alpha- and beta-neutral and only adds variance. Therefore the best trade-off between alpha and the variance of the regression residual is achieved for those returns in which only the first two components are present. The solution to Eq. (6) is characterized in Theorem 1.

Theorem 1. *The alpha of any payoff $x \in X_a$ is*

$$\alpha(x) = R_0 E[r_x(m_b - m_a)]. \tag{7}$$

The maximal appraisal ratio over all the payoffs in X_a is

$$\mathrm{APR}_{\max} = R_0 \|m_b - m_a\|, \tag{8}$$

and the maximum is achieved for any payoff x of the form

$$x = z + \theta(m_b - m_a) \tag{9}$$

for some $z \in X_b$ and $\theta > 0$.

The proofs of the theorems are in the Appendix.

Theorem 1 is closely linked to earlier analyses of payoff spaces. This should not surprise a reader familiar with the interpretation of asset payoffs as elements of Hilbert spaces. Numerous papers have studied asset payoffs in that context. The closest earlier pieces appear to be Chamberlain and Rothschild (1983), Hansen and Richard (1987), and Hansen and Jagannathan (1991, 1997).

Hansen and Jagannathan (1997) apply the properties of L^2 norms to the comparison of asset pricing models. The right-hand side of Eq. (8) is the product of R_0 and the L^2 norm of $m_b - m_a$; the latter term can also be interpreted as the Hansen and Jagannathan (HJ) distance of m_b from the set of discount factors that price all payoffs in X_a. The HJ distance is

$$\delta = \min\{\|m_b - m\| : m \in M_a\}. \tag{10}$$

Any discount factor $m \in M_a$ can be written as $m = m_a + (m - m_a)$ with $E[(m - m_a)x] = 0$ for all $x \in X_a$. It follows from $m_b - m_a \in X_a$ that

$$\|m_b - m\|^2 = \|m_b - m_a\|^2 + \|m - m_a\|^2. \tag{11}$$

The minimum of $\|m_b - m\|$ over $m \in M_a$ is achieved when $\|m - m_a\| = 0$, and thus $\mathrm{APR}_{\max} = R_0 \delta$. In this interpretation, m_b is understood as a given asset pricing model, and δ measures the misspecification of the model.

The maximal appraisal ratio is related to the variance bounds derived by Hansen and Jagannathan (1991). With R_0 denoting the safe rate, Eq. (8) reduces to

$$\mathrm{APR}_{\max} = R_0 \sqrt{\mathrm{var}(m_a) - \mathrm{var}(m_b)} \tag{12}$$

because $E[m_b m_a] = \|m_b\|^2$ and $E[m_b] = E[m_a] = 1/R_0$. According to Hansen and Jagannathan, $\mathrm{var}(m_a)$ is the greatest lower bound of the variance of the stochastic discount factors in M_a, and the same statement holds for $\mathrm{var}(m_b)$ and M_b. It then follows from Eq. (12) that the square root of the difference between the two variance bounds gives the maximal squared appraisal ratio discounted by R_0.

The maximal appraisal ratio is also related to the Sharpe ratios of the payoff spaces X_b and X_a, which are

$$\mathrm{SHP}_i = \max\{E[r_x]/\mathrm{var}(r_x)^{1/2} : x \in X_i\} \quad \text{for } i = a,b. \tag{13}$$

According to Hansen and Jagannathan (1991), the Sharpe ratio of a payoff space is the standard deviation of the smallest norm discount factor scaled by the safe return, i.e.,

$$\mathrm{SHP}_i = R_0 \sqrt{\mathrm{var}(m_i)} \quad \text{for } i = a,b, \tag{14}$$

which imply

$$\mathrm{APR}_{\max} = \sqrt{\mathrm{SHP}_a^2 - \mathrm{SHP}_b^2}. \tag{15}$$

Therefore, as one enlarges the payoff space from X_b to X_a, the improvement in the squared Sharpe ratio is the squared maximal appraisal ratio $\mathrm{APR}_{\max}$. The relation between the appraisal ratio and the Sharpe has appeared in the literature under various specialized assumptions. Goetzmann, Ingersoll, Spiegel, and Welch (2007) derive this relation for the case in which security prices are discrete [see Eq. (7) in that paper] and markets are complete. In the case that X_a consists of payoffs of the benchmarks and a set of additional assets, $\mathrm{APR}_{\max} = 0$ if and only if the efficient frontier of X_a is spanned by X_b, as discussed by Huberman and Kandel (1987). The simplest version of Eq. (15), in which X_b consists of only the market return and X_a includes an additional stock return, can be traced back to Treynor and Black (1973).

In summary, Theorem 1 covers or implies multiple existing results in the literature. Besides its generality, the theorem allows novel applications, which appear in Sections 3 and 4, in the analysis of maximal performance ratio and derivative trading.

2.2. Maximizing alpha

Theorem 1 considers maximization of the appraisal ratio and offers the solution to the maximization of alpha itself. Because alpha scales with leverage, if there is a zero price payoff with non-zero alpha, then there are payoffs with arbitrarily large alphas. In practice, such large alphas might not be attainable at least for two reasons: limits on risk and collateral requirements, both of which imply constraints on leverage.

First, money managers might not exceed a certain level of risk. A typical risk management mandate entails that the tracking error (TE), defined as the standard deviation of the hedged payoff, be lower than a certain upper bound TE:

$$\sqrt{\mathrm{var}(r_x - r'_m \beta)} \leq \mathrm{TE}. \tag{16}$$

Thus, a manager with such a mandate chooses a payoff of the form

$$x = z + \mathrm{TE} \frac{m_b - m_a}{\sqrt{\mathrm{var}(m_b) - \mathrm{var}(m_a)}}, \tag{17}$$

where z is an arbitrary payoff in the benchmark space. Such a choice scales a payoff with maximum appraisal ratio to the maximum tracking error allowed, obtaining a maximum alpha equal to the maximum appraisal ratio, times the maximum tracking error:

$$\alpha_{\max} = \mathrm{APR}_{\max} \mathrm{TE} = R_0 \sqrt{\mathrm{var}(m_b) - \mathrm{var}(m_a)} \mathrm{TE}. \tag{18}$$

Second, managers face collateral requirements, which depend on the riskiness of the total position, and

effectively limit their leverage.[3] Assume, as an approximation, that a zero-price payoff requires a margin proportional to its standard deviation, and denote by c the margin required for a unit standard deviation. Thus, the manager concentrates capital on the position that maximizes alpha per unit of standard deviation, and this position is precisely $m_b - m_a$. If the manager's capital is w, the alpha-maximizing position is

$$x = \frac{w}{c} \frac{m_b - m_a}{\sqrt{\text{var}(m_b) - \text{var}(m_a)}} \qquad (19)$$

and the corresponding maximum alpha is directly proportional to the available capital w and inversely proportional to the margin requirement c:

$$\alpha_{\max} = \text{APR}_{\max} \frac{w}{c} = R_0 \sqrt{\text{var}(m_b) - \text{var}(m_a)} \frac{w}{c}. \qquad (20)$$

In summary, the maximal alpha that can be achieved in practice is limited by institutional constraints, which imply directly or indirectly leverage bounds. With such bounds, the optimal strategy is to invest the maximum allowed amount in the payoff maximizing the appraisal ratio.

3. Maximal performance in a complete market

This section studies the implications of Theorem 1 under the standard assumption that the benchmark assets follow a geometric Brownian motion. Section 3.1 offers explicit formulas for the maximal Sharpe and appraisal ratios, in general, and then approximates these results for the limiting case that the observation interval is small. The intuition of this limiting case is transparent. Section 3.2 offers numerical examples, demonstrating that under the Black-Scholes assumptions it would typically take a long time for a manager who has no superior information and augments his portfolio with options to produce a positive alpha that is statistically significant.

3.1. Theoretical results

As Eq. (15) shows, the maximal appraisal ratio can be calculated from the Sharpe ratios of X_a and X_b. The calculation of the Sharpe ratio of X_b is straightforward from the moments of the benchmark returns because

$$\text{SHP}_b = \sqrt{E[r'_m][\text{var}(r_m)]^{-1}E[r_m]}. \qquad (21)$$

Similarly, if the attainable space X_a is spanned by a finite number of observable asset returns, it is straightforward to calculate the Sharpe ratio SHP_a from the moments of asset returns in X_a. The maximal appraisal ratio $\text{APR}_{\max}$ then follows from Eq. (15) as the square root of the difference between SHP_a^2 and SHP_b^2.

Because the space X_a could contain infinitely many security payoffs, the Sharpe ratio of X_a is more difficult to

obtain than that of X_b. In this subsection, for a given benchmark space X_b, the attainable space X_a is assumed to be the set of all L^2-integrable functions of the benchmark payoffs. That is, $X_a = L^2(P, \Omega)$, where $L^2(P, \Omega)$ is the set of all square integrable functions of the benchmarks. In this case, the market of X_a is said to be complete, and m_a is the minimum norm stochastic discount factor in $L^2(P, \Omega)$.

An important practical issue is the analysis of the payoff space that can be generated from trading derivatives on the benchmark assets. It is taken up next under the assumption that the prices of the benchmark assets follow a multivariate geometric Brownian motion. If the vector of the instantaneous annualized expected returns on the benchmark assets is $\mu = (\mu_1, \ldots, \mu_k)'$, under the assumption of geometric Brownian motion, the price of benchmark asset j at time t is

$$S_{j,t} = S_{j,0} e^{(\mu_j - 0.5\sigma_j^2)t + \sigma B_{jt}}, \quad 1 \le j \le k, \qquad (22)$$

where B_{jt} is a Brownian motion, σ_j is its annualized volatility, and S_{j0} is the price at $t=0$. The Brownian motions can be correlated. Let the correlation between B_{jt} and B_{lt} be ρ_{il}. Then, $B_t = (B_{1t}, \ldots, B_{kt})' \sim N(0_k, t\Sigma)$, where the covariance matrix Σ has $\rho_{jl}\sigma_j\sigma_l$ as the element on the j-th row and l-th column and is assumed positive-definite. During the time interval $[t, t+\Delta t]$, where time is measured in years, the return on benchmark asset j is $R_j = S_{j,t+\Delta t}/S_{j,t}$. If the instantaneous annualized safe rate is denoted by r, the return on the safe asset during the same time interval is

$$R_0 = e^{r\Delta t}. \qquad (23)$$

The parameters of the geometric Brownian motion are restricted by the moments of the benchmark excess returns. Because the j-th benchmark excess return is $r_j = R_j - R_0$, its expectation satisfies

$$E[r_j] = e^{r\Delta t}(e^{(\mu_j - r)\Delta t} - 1), \quad j = 1, \ldots, k. \qquad (24)$$

The variance of the j-th benchmark excess return satisfies

$$\text{var}(r_j) = e^{2r\Delta t}e^{2(\mu_j - r)\Delta t}(e^{\sigma_j^2 \Delta t} - 1), \quad j = 1, \ldots, k. \qquad (25)$$

The covariance between r_j and r_l satisfies

$$\text{cov}(r_j, r_l) = e^{2r\Delta t}e^{[(\mu_j - r) + (\mu_l - r)]\Delta t}(e^{\rho_{jl}\sigma_j\sigma_l\Delta t} - 1)$$
$$\text{for } j, l = 1, \ldots, k; \ j \ne l. \qquad (26)$$

If the moments of the excess returns are given, Eqs. (23)–(26) can be used to obtain the parameters in the geometric Brownian motion. The converse also holds: If the parameters of the geometric Brownian motion are given, these equations can be used to calculate the first two moments of r_m and then be substituted into Eq. (21) to obtain the Sharpe ratio of X_b.

Under the assumptions of geometric Brownian motion, which implies complete market, the maximal appraisal ratio can be obtained from Eq. (15) as derived in the Appendix. The result is as follows.

Theorem 2. *If the prices of the benchmark assets follow the geometric Brownian motion (Eq. (22)), the Sharpe ratio*

---

[3] As an example, since April 2007 the Chicago Board of Options Exchange calculates the daily collateral requirement of a position in options with the same underlying as the maximum loss on the total position, assuming changes in the underlying asset ranging from −8% to +6% for a broad-based index and from −10% to 10% for a non-broad-based index. See http://www.sec.gov/rules/sro/cboe/2006/34-54919.pdf.

generated from derivatives or delta trading strategies is

$$\text{SHP}_a = \sqrt{e^{(\mu-r1_k)'\Sigma^{-1}(\mu-r1_k)\Delta t}-1}. \tag{27}$$

Once the Sharpe ratios of X_b and X_a are calculated, the maximal appraisal ratio can be obtained from Eq. (15), which becomes

$$\text{APR}_{\max} = \sqrt{e^{(\mu-r1_k)'\Sigma^{-1}(\mu-r1_k)\Delta t}-E[r'_m][\text{var}(r_m)]^{-1}E[r_m]-1}, \tag{28}$$

where $E[r_m]$ and $\text{var}(r_m)$ can be calculated from Eqs. (24)–(26). An important feature of the $\text{APR}_{\max}$ in Eq. (28) is that it approaches to zero if the observation interval Δt shrinks to zero or if the vector of risk premiums $\mu-r1_k$ drops to zero.

To see the exact relation between the maximal appraisal ratio and the risk premium, Eq. (28) is simplified. Without loss of generality, the benchmark excess returns can be chosen orthogonal to each other. In this case, $\rho_{jl}=0$ for all $j\neq l$. Denote the annualized Sharpe ratio of the j-th benchmark by s_j, which equals $(\mu_j-r)/\sigma_j$, and let $s=(s_1,\ldots,s_k)'$. The maximal appraisal ratio becomes

$$\text{APR}_{\max} = \sqrt{e^{(s's)\Delta t}-\sum_{j=1}^{k}e^{-2s_j\sigma_j\Delta t}(e^{s_j\sigma_j\Delta t}-1)^2(e^{\sigma_j^2\Delta t}-1)^{-1}-1}. \tag{29}$$

The first-order approximation of Eq. (29) in terms of Δt is

$$\text{APR}_{\max} = \{s'[\Sigma+2\text{Diag}(\mu-r1_k)]s+(s's)^2\}^{1/2}\frac{\Delta t}{\sqrt{2}}+O(\Delta t^2), \tag{30}$$

where $\text{Diag}(\mu-r1_k)$ is the $k\times k$ diagonal matrix in which the j-th diagonal element is μ_j-r. In the case of a single benchmark (setting $k=1$ and dropping off the subscripts of μ_1, σ_1, and s_1), the formula of the maximal appraisal ratio simplifies to

$$\text{APR}_{\max} = \sqrt{e^{s^2\Delta t}-e^{-2s\sigma\Delta t}(e^{s\sigma\Delta t}-1)^2(e^{\sigma^2\Delta t}-1)^{-1}-1}, \tag{31}$$

and its first-order approximation is

$$\text{APR}_{\max} = (\mu-r+s^2)\frac{\Delta t}{\sqrt{2}}+O(\Delta t^2). \tag{32}$$

According to the approximation, the maximal appraisal ratio is positively associated with the annualized risk premium μ_j-r and the annualized Sharpe ratio s_j of each benchmark.[4] It is also positively associated with time interval between the evaluator's two consecutive observations. This is reasonable because a longer observation period increases the manager's attainable space by delta trading or, equivalently,

allows for more effective exploitation of the nonlinearity associated with the option payoffs.

The previous formulas remain valid in the presence of additional securities other than the benchmarks, which carry extra unpriced idiosyncratic risk. Put differently, using options on individual securities cannot improve the appraisal ratio if the returns on the benchmark assets span the risk factors and the options on the benchmarks are used optimally.

To understand this argument, consider a market in which, in addition to the k log-normally distributed benchmark asset returns, r_{jt} for $1\leq j\leq k$, there are n securities with excess returns r_{it} for $k+1\leq i\leq k+n$, given by

$$r_{it} = \sum_{j=1}^{k}\beta_{ij}r_{jt}+\varepsilon_{it}, \tag{33}$$

where β_{ij} are constants, ε_{it} for $k+1\leq i\leq k+n$ are random variables that are independent of the benchmarks and of each other, and $E[\varepsilon_{it}]=0$. In other words, these securities are exposed to unpriced idiosyncratic risks. Both discount factors price all the additional securities because $E[\varepsilon_{it}]=0$ and ε_i is uncorrelated with the benchmark returns. Therefore, the discount factors m_a and m_b are the same as in the market consisting of the benchmark assets alone.

3.2. Numerical results

In performance evaluation, the benchmark payoffs are often the factors used in the studies of the linear asset pricing models. The first factor is usually the market factor (MKT), which is the excess return on the value-weighted aggregate equity index compiled by the Center for Research in Security Prices (CRSP). Three additional factors are used by researchers, e.g., Fama and French (1993, 1996), to explain average stock returns: The firm-size factor (SMB) captures the firm-size premium examined by Banz (1981), the book-to-market factor (HML) captures the value premium presented by Stattman (1980), and the momentum factor (MOM) captures the profit of momentum trading strategy reported by Jagadeesh and Titman (1993). The monthly observations of these factors are available at Kenneth French's web site, which also provides the returns on one-month Treasury bills (TBL). The sample of monthly excess returns on the factors from January 1963 to December 2006 are displayed in Panel A of Table 1. Panel B reports the geometric Brownian motion parameters that are consistent with the sample moments. These parameters are solved from Eqs. (23)–(26).

Consider three benchmark spaces: (1) X_b^{CA} is the benchmark space spanned by the MKT factor [CA alludes to the Capital Asset Pricing Model] and the safe return; (2) X_b^{FF} is the benchmark space spanned by the MKT, SMB, and HML factors and the safe return; and (3) X_b^{MM} is the benchmark space spanned by the MKT, SMB, HML, and MOM factors and the safe return. The Sharpe ratios of these benchmark spaces can be calculated using Eq. (21) based on the parameters in Table 1 and various assumptions on the time interval Δt of observations. Column B of Table 2 reports the Sharpe ratios of the benchmark spaces for monthly ($\Delta t=1/12$), quarterly

---

[4] Fig. 1 helps bring understanding to the relation between the appraisal ratio and the risk premium. Holding all other parameters fixed, an increase in the risk premium implies an increase in the slope of the dashed line representing the index return as well as an increase in the Sharpe ratio. Therefore, the intercept of the dotted regression line increases, showing a higher alpha. Because other parameters are being held constant, it follows that a higher alpha is associated with a higher appraisal ratio.

$(\Delta t = 1/4)$, and semiannual $(\Delta t = 1/2)$ observations. As expected, a larger benchmark space or a longer observation period is associated with higher Sharpe ratios. For example, the Sharpe ratio of X_b^{MM} is 0.631 for quarterly observation,

Table 1
Estimated parameters for the factors.

Panel A reports the sample means, standard deviations, covariances, correlations, and Sharpe ratios of the monthly excess returns on the market (MKT), firm-size (SMB), book-to-market (HML), and momentum (MOM) factors from January 1963 to December 2006. It also reports the average monthly Treasury bill rates (TBL). Variable definitions are in the text. The data of the monthly excess returns are from Kenneth French's website http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html. Panel B presents the geometric Brownian motion parameters consistent with the sample means and covariances of the monthly returns. These parameters are annualized and solved from Eqs. (23)–(26).

Statistic	TBL	MKT	SMB	HML	MOM
Panel A: Sample moments of monthly returns					
Mean	0.47%	0.49%	0.25%	0.47%	0.82%
Standard deviation		1.26%	0.93%	0.83%	1.15%
Sharpe ratio		0.112	0.077	0.162	0.205
Correlation					
MKT			0.301	−0.409	−0.064
SMB				−0.280	0.022
HML					−0.115
Panel B: Parameters in geometric Brownian motion					
Growth rate	5.6%	11.4%	8.5%	11.2%	15.3%
Volatility		15.0%	11.0%	9.9%	13.6%
Sharpe ratio		0.390	0.266	0.564	0.712
Correlation					
MKT			0.302	−0.409	−0.064
SMB				−0.280	0.022
HML					−0.115

higher than the ratio for monthly observation, which is 0.367. The quarterly Sharpe ratio of X_b^{MM} is also higher than the Sharpe ratio of X_b^{FF} for the same quarterly observation frequency, which is 0.463.

Let X_a^i be the payoff space that contains all the functions (with finite second moment) of the benchmarks in X_b^i, for $i =$ CA, FF, and MM. In the absence of derivative securities on these factors, the payoffs in X_a^{CA}, X_a^{FF}, and X_a^{MM} must be achieved by delta trading. The Sharpe ratios of the payoff spaces can be calculated using Eq. (27) and the parameters in Table 1. Column 3 of Table 2 reports the Sharpe ratios of the attainable spaces for monthly, quarterly, and semiannual observations. Again, as expected, a larger attainable space or a longer observation period is associated with higher Sharpe ratios, and the Sharpe ratio of an attainable space is always higher than its corresponding benchmark space. For quarterly observations, as an example, the Sharpe ratio of X_a^{MM} is 0.708, higher than the Sharpe ratio of X_b^{FF}, which is 0.631.

By Eq. (15), the squared difference between the Sharpe ratios of the benchmark and attainable spaces gives the maximal appraisal ratio (namely, APR_{max}), which is reported in Column 4 of Table 2. In each observation frequency, the maximal appraisal ratio increases at least fourfold when the SMB and HML factors are added to the benchmark space. When the MOM factor is further added to the benchmark space, the maximal appraisal ratio is nearly doubled. For example, in quarterly observations, APR_{max} is 0.037 when the benchmark space is X_b^{CA} but increases to 0.171 when the benchmark space is enlarged to X_b^{FF}. It goes up to 0.322 when the MOM factor is added. The strategy maximizing the appraisal ratio also maximizes alpha, controlling for risk. Column 5 reports the maximal alpha, subject to the constraint that the annualized tracking error does not exceed a generous 10%.

Table 2
Performance with factors as benchmarks.

Three sets of benchmark assets (and their corresponding payoff spaces) are considered: the safe asset and market factor (MKT), the safe asset, MKT, firm-size (SMB), and book-to-market (HML), and the safe asset, MKT, SML, HML and momentum (MOM). Variable definitions are in the text. Three observation frequencies are considered: monthly, quarterly, and semiannual. Using the data and parameters in Table 1, for each benchmark set and each observation period, the following are estimated: Sharpe ratio of the benchmark space (Column 2), Sharpe ratio of the space generated by the benchmark space and delta trading on its members (Column 3), the maximal appraisal ratio of the space according to Theorem 2 (Column 4), the annualized maximal alpha when constraining the annualized tracking error to be no more than 10% (Column 5), the approximate minimum number of years it would take to obtain a significantly positive alpha *t*-statistics in the regression of the returns of the optimal delta trading strategy on returns of the benchmark assets (Column 6), and the probability of incurring a loss by a benchmark-neutral portfolio that maximizes alpha (Column 7).

Observations (1)	Sharpe ratio of benchmark (2)	Sharpe ratio of attainable (3)	Maximal appraisal ratio (4)	Maximal alpha (annual) (5)	Minimal years for significance (6)	Probability to incur a loss (7)
Monthly						
MKT	0.112	0.113	0.012	0.43%	2,084	0.495
MKT, SMB, HML	0.269	0.275	0.056	1.93%	103	0.478
MKT, SMB, HML, MOM	0.367	0.381	0.103	3.56%	30	0.459
Quarterly						
MKT	0.193	0.197	0.037	0.74%	694	0.485
MKT, SMB, HML	0.463	0.494	0.171	3.42%	33	0.432
MKT, SMB, HML, MOM	0.631	0.708	0.322	6.44%	9	0.374
Semiannual						
MKT	0.271	0.281	0.074	1.05%	346	0.470
MKT, SMB, HML	0.649	0.739	0.354	5.00%	15	0.362
MKT, SMB, HML, MOM	0.883	1.120	0.689	9.75%	4	0.245

(In practice, money managers aim to have a tracking error no greater than 2–3%.)

The positive alpha is difficult to realize if one examines the statistical significance of alpha samples and the probability for a sample to be negative. The t-statistic of alpha can be approximated by the product of APR_{max} and the squareroot of the number of observations n. A significant t-statistic at 95% confidence level requires $\sqrt{n} \times APR_{max} > 1.96$. Then, $n = (1.96/APR_{max})^2$ is approximately the minimum number of observations to obtain a significant t-statistic. These numbers are reported in Column 6 of Table 2. Column 7 reports the probability that alpha turns out to be negative. It is noteworthy that these numbers are calculated assuming zero trading costs, which favors a higher alpha and a lower probability of alpha being negative than what one can realistically expect.

Two patterns emerge from Table 2: As the benchmark space increases and as the observation period increases the appraisal ratio increases (and therefore the minimal number of years to obtain a significant t-statistic decreases). The appraisal ratio increases because the risk premium and Sharpe ratio of the benchmark space increase as more indices are added to the benchmark space. Table 1 shows that HML and MOM factors have relatively high growth rates. Table 2 shows that inclusion of HML and MOM evidently increases the Sharpe ratio. As indicated by Theorem 2 and Eq. (32), the appraisal ratio is positively related to the risk premia of benchmark assets and the Sharpe ratio of the benchmark space.

Wang and Zhang (2003) anticipate these observations. Studying the frequency and magnitude with which pricing kernels associated with certain benchmarks take on negative values, they note that such negative values are relatively rare and small when the benchmark space is spanned by the market portfolio but become increasingly more frequent and larger as SMB and HML are added as benchmark portfolios. Negativity of the pricing kernel suggests that by trading options one can outperform the returns spanned in the benchmark space.

4. Performance enhancement through option writing

Fig. 1 suggests that the most intuitive way to appear to be outperforming is by writing options. This section explores this intuition, arguing that one can deliver the optimal policy exclusively by writing options. Section 4.1 applies Theorem 1 to describe the optimal option writing strategy. The relation between the pricing of the options and the process generating the benchmark returns is important for the assessment of the appraisal ratio that the optimal policy is likely to generate.

Section 4.1 studies these maximal appraisal ratios under the assumption that the S&P 500, Nasdaq 100, and Russell 2000 indices follow a geometric Brownian motion and that, therefore, the Black-Scholes formula correctly prices options on these indices with the volatility of the underlying geometric Brownian motion process. Under these assumptions it turns out that a fund manager who cannot predict future returns is unlikely to generate a statistically reliable alpha by trading derivatives, even though a positive alpha is expected ex ante.

Departures from geometric Brownian motion price evolution and the associated Black-Scholes option pricing have been studied, e.g., in Jones (2006) and Broadie, Chernov, and Johannes (2007). Section 4.2 relaxes the geometric Brownian motion assumption and allows options to be priced at the actual implied volatility instead of at the volatility of the stochastic process governing the underlying asset. In this setup, option payoffs cannot always be replicated by delta trading and, therefore, options are not redundant assets. In this more general case it is possible to generate a statistically reliable alpha. A comparison between this more general case and the preceding one indicates that an alpha is likely to emerge even for the manager who cannot predict future returns not because of the nonlinear nature of the payoff on the options but because of market incompleteness, i.e., because the option prices reflect departures from the assumptions in the Black-Scholes model.

4.1. When physical and implied volatilities coincide

Under the assumption of geometric Brownian motion, the solutions to the performance maximization problem in equation (6) are combinations of the benchmark payoffs and the variable $m_b - m_a$, which is a nonlinear function of the benchmark payoff. When the benchmark space consists of only one risky asset (in addition to the safe asset), the expression of the optimal payoff as function of the benchmark return R_m can be derived.

Theorem 3. *Assume that the benchmark space consists of only one risky asset and its price follows a geometric Brownian motion with growth rate μ and volatility σ. Assume the continuously compounded safe rate is r. Then, for any numbers γ and ϕ and any positive number θ, the payoff satisfies*
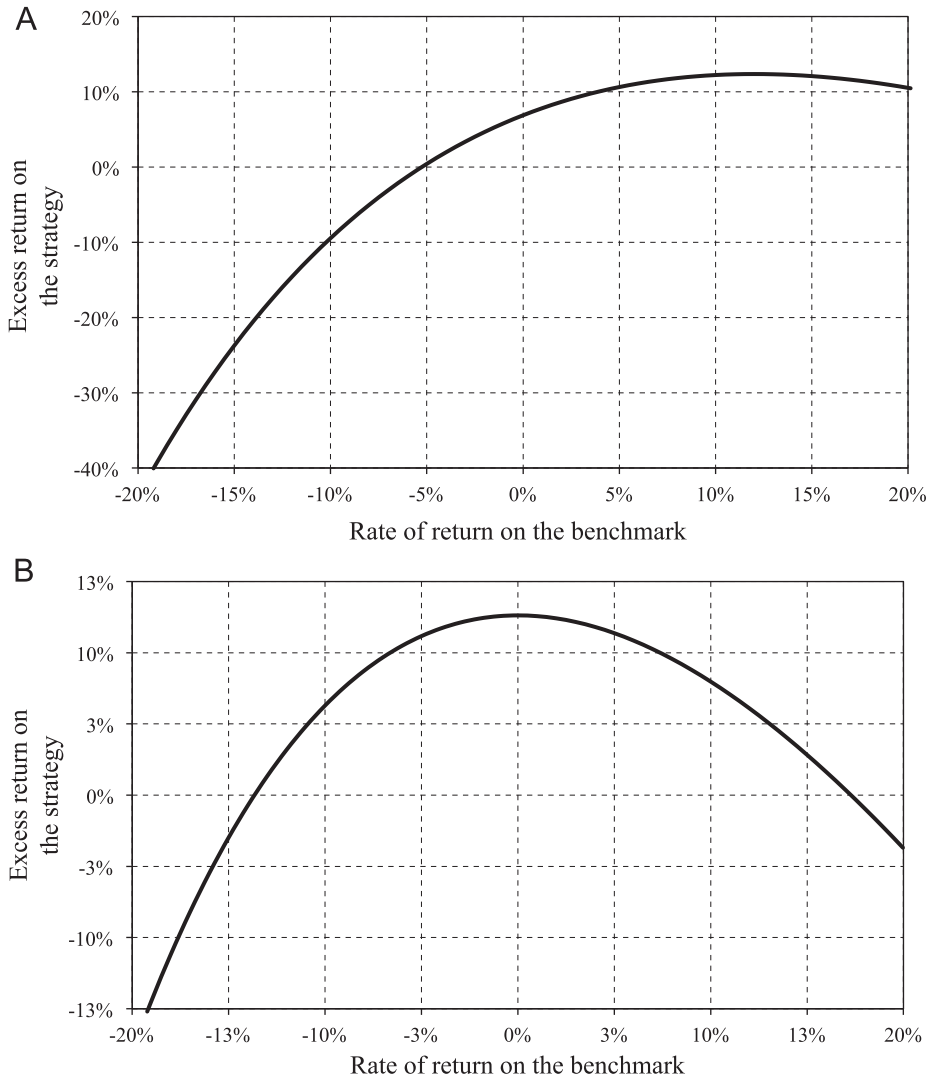

$$x = \gamma + \phi R_m - \theta f(R_m), \tag{34}$$

where

$$f(R_m) = c R_m^{-b} \quad \text{with } b = (\mu - r)/\sigma^2; \; c = e^{[-r + 0.5b(\mu + r - \sigma^2)]\Delta t}, \tag{35}$$

solves the optimization problem equation (6).

The payoff of the optimal strategy in Eq. (34) is a nonlinear function of R_m because the function f is nonlinear. The first derivative of the function is negative ($f' < 0$) and its second derivative is positive ($f'' > 0$). To show the nonlinear nature of the optimal strategies, Panel A of Fig. 2 displays the excess return on a one dollar investment in the strategy as a function of the rate of return on the benchmark index. The parameters in the stochastic process of the index are $\mu = 11.43\%$, $\sigma = 14.98\%$, and $r = 5.59\%$ per annum, which are the estimates for the market factor and T-bills rate in Table 1. The parameter θ is set to one. The parameter ϕ is chosen so that the strategy's delta with respect to the benchmark is one. To make x a return on one dollar investment, γ is chosen so that the value of the strategy is 1. All the returns in the figure are annualized by setting $\Delta t = 1$.

Fig. 2. The nonlinear returns on the optimal strategy. Panel A displays the excess return on a one dollar investment in the optimal strategy in Eq. (34) as a function of the rate of return on the benchmark. Panel B displays the excess return on one dollar investment in the hedged optimal strategy. The parameters in the stochastic process of the benchmark are $\mu = 11.43\%$, $\sigma = 14.98\%$ and $r = 5.59\%$ per annum. The parameter θ is set to one. In the unhedged strategy, ϕ is chosen so that the strategy's delta with respect to the benchmark is one, whereas in the hedged strategy ϕ is chosen so that its delta is zero. In each strategy, γ is chosen so that the value of the strategy is one. All the returns in the figure are annualized by setting $\Delta t = 1$.

Panel B of Fig. 2 displays the excess return on a one dollar investment in the optimal strategy that is benchmark-neutral. In the benchmark-neutral strategy, ϕ is chosen so that its delta with respect to the benchmark is zero, implying $\text{cov}(r_x, r_m) \approx 0$. The parameter θ is again set to one, and γ is chosen so that the value of the hedged strategy is one. The excess return on the hedged strategy stays positive as long as the rate of return on the benchmark is between -13% and 17%. This means that the hedged strategy is profitable as long as the benchmark stays within the range around the current level. In practice, the profitable range should be narrower due to transaction costs and borrowing rates that are higher than the safe return. Losses occur when the benchmark rises or drops outside of the range.

The optimal strategy can be implemented by writing options on the benchmarks because the nonlinear part $f(R_m)$ can be replicated by a portfolio of call and put options. In fact, integration by parts shows that for any $K > 0$ and any twice differentiable function f,

$$f(R_m) = f(K) + f'(K)(R_m - K)$$

$$+ \int_0^K f''(k)(k - R_m)^+ \, dk + \int_K^\infty f''(k)(R_m - k)^+ \, dk.$$

$$\tag{36}$$

The first and second integrations in Eq. (36) sum the payoffs of long positions in put and call options, respectively. Eqs. (34) and (36) indicate that the strategy that

achieves the highest appraisal ratio involves writing a set of options.

If $K=1$ and $\theta=1$, the payoff of the performance-maximizing strategy is

$$\hat{x} = \hat{\gamma} + \hat{\phi} R_m - \int_0^1 f''(k)(k-R_m)^+ \, dk - \int_1^\infty f''(k)(R_m-k)^+ \, dk, \tag{37}$$

where $\hat{\gamma} = \gamma + (b-1)c$ and $\hat{\phi} = \phi + bc$. The first integration of Eq. (37) is over payoffs of out-of-the-money put options, and the second integration is over payoffs of out-of-the-money call options. Therefore, the optimal strategy can be implemented by writing out-of-the-money options on the benchmark.
The strategy in Eq. (37) can be approximated by taking positions in options with discrete grids of moneyness k.

For example, let $\Delta k = 1\%$ and $k_i = i\Delta k$. In this strategy the position in the call or put options out of the money by $100|1-k_i|$ percent is $-f''(k_i)\Delta k$ units. For a one dollar investment in the strategy and the same parameters used in Fig. 2, Panel A of Fig. 3 displays $-f''(k_i)\Delta k$. It is an increasing function of k_i. Thus, the strategy of Eq. (37) shorts more puts than calls. Also, the strategy shorts more puts when they are more out of the money. In contrast, the strategy shorts fewer calls that are more out of the money.

In the strategy in Eq. (37) the value of the short position on an option decreases fast as the option moves further out of the money. Use $h(k)$ to denote the price of a call (put) options on R_m with strike price $k \geq 1$ ($k < 1$) and maturity Δt. Then, $h(k_i)f''(k_i)\Delta k$ is the premium collected from writing the call or put option that is out of the money by $100|1-k_i|$ percent. If the parameters are chosen

Fig. 3. Options position that maximizes the appraisal ratio. For a one dollar investment in the optimal strategy in Eq. (37), Panel A displays the positions in the options of each 1% of moneyness k. Panel B displays the portfolio weight on the options of each 1% of moneyness k. The parameters in the stochastic process of the benchmark are $\mu = 11.43\%$, $\sigma = 14.98\%$, and $r = 5.59\%$ per annum, same as those used in Fig. 2.

Fig. 4. Delta of the options in the optimal strategy. Each of the curves from bottom to top is the number of shares in the underlying asset, as a function of the asset price itself, at one month, three months, six months, and one year before expiration. Original asset price is normalized to one.

so that the value of the payoff $\hat{x}$ is one dollar, then $-h(k_i)f''(k)\Delta k$ is the portfolio weight on the options with moneyness k_i. The portfolio weights are plotted in Panel B of Fig. 3, which shows that, in terms of option premiums collected, the strategy writes more options near the money than the options far out of the money.

The short leg of the performance-ratio maximization strategy implies that its delta, the sensitivity of the strategy's value to the index price, decreases as the time passes or as the index price rises. The delta of the strategy decreases as time passes because the delta of each call or put option is an increasing function of the time-to-maturity. Because each call or put option has a positive gamma, which is the sensitivity of delta to the index price, the strategy has a negative gamma, implying that its delta is a decreasing function of the index price. Fig. 4 illustrates the delta of the performance maximization strategy for different levels of the index price and different time-to-maturity.

The maximal performance ratios relative to the S&P 500 (SPX), Nasdaq 100 (NDX), and Russell 2000 (RUT) indices are examined next because these indices often serve as benchmarks for evaluation of actively managed funds and options on these indices are actively traded. The daily realized index returns from February 23, 1985 to April 30, 2007, are used to estimate the relevant parameters. The resultant Sharpe ratios of the benchmark spaces and of the attainable spaces are reported in Table 3. The maximal appraisal ratios of the payoff spaces that contain all the derivatives on the benchmarks as well as the approximate number of years required to attain significant expected t-statistics are also provided.

The attainable payoff spaces underlying the reported calculations are larger than the actual available derivative payoff spaces in that the calculations assume the availability of all derivatives. Actual index options are not available at all strike prices. Thus, the estimated Sharpe

ratios of the attainable spaces and the appraisal ratio are biased upward.

The expected alphas of the Sharpe ratio-maximizing strategies analyzed here are positive and substantial in magnitude. Table 3, however, suggests that it should be difficult to generate statistically significant alpha from trading options on the S&P 500, Nasdaq 100 and Russell 2000 indices. The results for MKT in Table 2 and those for SPX in Table 3 are similar because the returns of the two indices are highly correlated. More generally, the messages of Tables 2 and 3 are similar. It will take more than a thousand years to generate statistically significant alpha if it is estimated from monthly returns. For example, with the SPX as the benchmark, 1,803 years is the expected minimum time required to obtain a statistically significant alpha by writing options on the SPX. If alpha is estimated from quarterly or semiannual returns, it takes hundreds of years to generate statistically significant alpha by trading derivatives. Therefore, the attempt to generate a statistically significant alpha by trading index options is unlikely to succeed, so long as the benchmark returns follow a multivariate geometric Brownian motion and options are priced accordingly.

Table 4 follows the structure of Table 3, but in it the Fama-French portfolios span the benchmark spaces. The table reflects a purely theoretical exercise because its construction ignores not only transactions costs (as does the construction of the other tables) but also the current absence of tradable options on the Fama-French portfolios. The results – especially for the case of 2×3 portfolios – indicate more room to generate alpha with lower uncertainty, if options on these portfolios were available or the cost of trading these portfolios is negligible.[5]

---

[5] We are grateful to the referee, who suggested considering this spanning benchmark spaces by Fama-French portfolios.

Table 3
Performance ratios with market indices as benchmarks.

    Three sets of benchmark assets (and their corresponding payoff spaces) are considered: the safe asset and SPX (the Standard & Poor's 500), the safe asset, SPX, and NDX (the Nasdaq 100), and the safe asset, SPX, NDX, and RUT (Russell 2000). Variable definitions are in the text. Three observation frequencies are considered: monthly, quarterly, and semiannual. For each benchmark set and each observation period, the following are estimated: Sharpe ratio of the benchmark space (Column 2), Sharpe ratio of the space generated by the benchmark space and delta trading on its members (Column 3), the maximal appraisal ratio of the space according to Theorem 2 (Column 4), the annualized maximal alpha, when constraining the annualized tracking error to be no more than 10% (Column 5), the approximate minimum number of years it would take to obtain a significantly positive alpha t-statistics in the regression of the returns of the optimal delta trading strategy on returns of the benchmark assets (Column 6), and the probability of incurring a loss by a benchmark-neutral portfolio that maximizes alpha (Column 7). The data of the indices are from Bloomberg.

Observations (1)	Sharpe ratio of benchmark (2)	Sharpe ratio of attainable (3)	Maximal appraisal ratio (4)	Maximal alpha (annual) (5)	Minimal years for significance (6)	Probability to incur a loss (7)

Table 4
Performance ratios with Fama-French portfolios as benchmarks.

    Three sets of benchmark assets (and their corresponding payoff spaces) are considered: the FF 2×3 portfolios, the FF 5×5 portfolios, and the FF 10×10 portfolios. Variable definitions are in the text. Three observation frequencies are considered: monthly, quarterly, and semiannual. For each benchmark set and each observation period, the following are estimated: Sharpe ratio of the benchmark space (Column 2), Sharpe ratio of the space generated by the benchmark space and delta trading on its members (Column 3), the maximal appraisal ratio of the space according to Theorem 2 (Column 4), the annualized maximal alpha when constraining the annualized tracking error to be no more than 10% (Column 5), the approximate minimum number of years it would take to obtain a significantly positive alpha t-statistics in the regression of the returns of the optimal delta trading strategy on returns of the benchmark assets (Column 6), and the probability of incurring a loss by a benchmark-neutral portfolio that maximizes alpha (Column 7). The data of the FF portfolios are obtained from Kenneth French's website http://mba.tuck.dartmouth.edu/pages/faculty/ken.french/data_library.html.

Observations (1)	Sharpe ratio of benchmark (2)	Sharpe ratio of attainable (3)	Maximal appraisal ratio (4)	Maximal alpha (annual) (5)	Minimal years for significance (6)	Probability to incur a loss (7)
Monthly						
FF 2×3 portfolios	0.370	0.386	0.112	3.87%	26	0.456
FF 5×5 portfolios	0.198	0.200	0.030	1.04%	356	0.488
FF 10×10 portfolios	0.213	0.216	0.035	1.20%	266	0.486
Quarterly						
FF 2×3 portfolios	0.629	0.719	0.348	6.96%	8	0.364

FF 10×10 portfolios	0.519	0.562	0.215	3.04%	41	0.415

4.2. When physical and implied volatilities differ

    The results reported in Section 4.1 appear to be inconsistent with the practical experience in generating alpha by writing index options. Lo (2001) reports a high Sharpe ratio from a strategy that entails holding the S&P 500 index and writing put options. In a similar vein, Hill, Balasubramanian, Krag, and Tierens (2006) report that a large alpha can be obtained from the strategy of buying the S&P 500 index and writing index call options. The attractiveness of the strategy led the Chicago Board of Options Exchange (CBOE) to create the BuyWrite monthly index (BXM) to track the return from the strategy of writing one month at-the-money call options every month. The regression of monthly excess returns on the BXM index with respect to the S&P 500 delivers significant t-statistics for the period from January 1990 to

December 2005 (see Table 5). The performance of the BXM index is especially good in the first subperiod.

The results reported in Table 5 are based on actual option prices as oppose to theoretical Black-Scholes prices. Empirical regularities inconsistent with the Black-Scholes model highlight a number of stylized facts. First, the implied volatility index (VIX) is consistently higher than the realized volatility of the underlying. Second, the implied volatility is higher for options more out of the money they are (the volatility smile) or the lower their strike prices (the volatility skew). Third, both implied and realized volatilities exhibit ample time variation across different strikes and maturities. The deviations from the Black-Scholes model as well as the nonlinearity of the payoffs could account for the excess performance of the BXM index. The rest of this subsection shows that the first stylized fact (i.e., the implied volatility being higher than the realized volatility) alone can account for a large part of the excess performance of the BXM index.

To apply the framework developed in this paper to the performance of the BXM index, one needs to identify the pricing kernels m_b and m_a. For simplicity, assume here a single risky benchmark asset whose return has a log-normal distribution. Options on it are priced according to the Black-Scholes formula, but possibly with a different implied volatility. Only options with single one-period maturity are considered and therefore there is no room for a term structure of implied volatilities. Moreover, all options of the same maturity are assumed to have the same implied volatility, thus abstracting from the volatility smile and skew. With the options having implied volatility different from that of the underlying asset, it is in general not possible to replicate the option payoffs by delta trading. Put differently, with these assumptions it is also assumed that the benchmark assets do not complete the market, and therefore options are not redundant assets.

In the market considered here, investment is made at time t and the return is received at time $t+\Delta t$. The continuously compounded safe rate is r. The return on the risky asset follows a log-normal distribution, i.e., the return is

$$R_m = e^{(\mu-0.5\sigma^2)\Delta t+\sigma\sqrt{\Delta t}}\psi, \tag{38}$$

where ψ is a standard normal random variable under the physical probability measure P. The parameters μ and σ are the physical growth rate and the physical volatility of the risky asset, respectively. From Eq. (38), it does not follow that the evolution of asset prices is governed by a geometric Brownian motion.

Derivative securities are also available in this market. The volatility according to which they are priced is the implied volatility, denoted by $\hat{\sigma}$. It is different from the physical volatility σ. Let $\lambda = \hat{\sigma}/\sigma$. Assume that all derivatives on the asset price with time-to-maturity Δt are priced by the implied volatility $\hat{\sigma}$. Then, the risk-neutral probability measure Q satisfies

$$E_Q[R_m] = e^{r\Delta t} \tag{39}$$

and

$$\text{var}_Q(\log R_m) = \hat{\sigma}^2\Delta t. \tag{40}$$

Let the benchmark payoff space X_b be spanned by the safe return and the return on the risky asset. To evaluate the performance generated from trading derivatives, let X_a be the payoff space spanned by X_b and its derivative securities, i.e., X_a is spanned by all the functions $f(R_m)$ with finite second moments. The assumed completeness of X_a implies that m_a is the unique stochastic discount factor (SDF) and thus has the smallest norm.

Theorem 4. *Under the assumptions in Eqs.* (38)–(40), *if* $0 < \lambda < \sqrt{2}$, *then the maximal appraisal ratio is*

$$\text{APR}_{\max}(\lambda) = [\lambda^{-1}(2-\lambda^2)^{-1/2}e^{\delta^2(2-\lambda^2)^{-1}\Delta t}$$
$$-e^{-2s\sigma\Delta t}(e^{s\sigma\Delta t}-1)^2(e^{\sigma^2\Delta t}-1)^{-1}-1]^{1/2}, \tag{41}$$

where $s = (\mu-r)/\sigma$ *and* $\delta = s+\sigma(\lambda^2-1)/2$.

When the implied volatility equals the physical volatility (i.e., $\lambda = 1$), the above equation reduces to Eq. (31). As the time interval Δt approaches zero, the maximum appraisal ratio approaches

$$\lim_{\Delta t\to 0}\text{APR}_{\max}(\lambda) = \sqrt{\frac{1}{\lambda\sqrt{2-\lambda^2}}-1}. \tag{42}$$

The above limit is zero if $\lambda = 1$ and is an increasing function of λ for $\lambda \in [1,\sqrt{2})$. Therefore, when the implied volatility is higher than the actual volatility, trading derivatives can lead to a high appraisal ratio even when the observation interval is very short. It is, however, difficult to accomplish this when the implied and physical volatilities are the same.

Table 6 shows that the relatively high implied volatility during 1990–2005 offered an opportunity for the derivative

Table 5
The alpha of the Buywrite monthly index (BXM), 1990–2005.

The alpha and the corresponding t-statistic of the BXM index are estimated by ordinary least squares regression of the monthly excess returns of the BXM index on the monthly excess returns of the Standard & Poor's 500 index. The data of the monthly indices are from Bloomberg.

Period	Annualized average return of S&P 500	Annualized average return of BXM	Annualized alpha of BXM over S&P 500	t-Statistic of alpha of BXM over S&P 500	p-Value of alpha of BXM over S&P 500
January 1990–December 2005	0.07	6.82%	2.66%	2.20	0.0144
January 1990–December 1994	0.04	6.55%	4.11%	2.59	0.0061
January 1995–December 1999	0.21	14.32%	2.41%	0.90	0.1864
January 2000–December 2005	−0.03	0.80%	2.53%	1.22	0.1138

Table 6
Maximal appraisal ratios with implied volatility greater than realized volatility.

The maximal appraisal ratios are calculated from Eq. (41). The historical volatility is estimated from the daily observations of the Standard & Poor's (S&P) 500 index for the each of the periods indicated in the table. The estimated implied volatility is the daily average of VIX for the corresponding period. The ratio of estimated implied volatility to the estimated historical volatility is the λ used in Eq. (41). The maximal alpha are computed under the constraint that the tracking error cannot exceed 10%. The last column is the probability of incurring a loss by a benchmark-neutral portfolio that maximizes alpha. The data of the S&P 500 index and VIX are from Bloomberg.

Period	Historical volatility of S&P 500	Implied volatility (VIX)	Ratio of implied to historical	Maximal appraisal ratio	Maximal alpha	Probability to incur a loss
January 1990–December 2005	16%	19%	1.21	5.77	4.16%	0.000
January 1990–December 1994	12%	17%	1.39	14.01	18.08%	0.000
January 1995–December 1999	16%	20%	1.27	7.96	10.28%	0.000
January 2000–December 2005	19%	21%	1.11	1.48	1.75%	0.069

trading strategy to perform well. During this period, the historical volatility estimated from the daily S&P 500 index is 16%, whereas the average VIX is 19%, giving $\lambda = 1.21$. Using Eq. (41) of Theorem 4, the maximal appraisal ratio of monthly returns during the period is $\sqrt{192} \times \text{APR}_{\max} = 5.77$. This is much higher than the realized performance ratio of 2.20 reported in Table 5 for the BXM index, but it points in the right direction. Various explanations for the discrepancy between the theoretical and actual performance ratios are readily available. First, the strategy in BXM – buying S&P 500 index and selling at-the-money call options – does not necessarily achieve the maximal performance, whereas the strategy underlying the numbers in Table 6 is optimal. Second, the theoretical analysis ignores temporal variations in the implied and physical volatilities. Third, the realized performance is based on a finite sample instead of an infinite sample as assumed for $\text{APR}_{\max}$. These discrepancies between the assumptions in Theorem 4 and the data could lead to the difference between the numbers reported in Tables 5 and 6.

One pattern is common to Tables 5 and 6, namely, that performance of the strategy was stronger in the earliest subperiod and deteriorated subsequently. Table 6 also shows that the opportunity offered by the high implied volatility declined over time. The ratio of implied-to-physical volatility was high ($\lambda = 1.39$) in the first five years of the sample in the table and fell in later subperiods. Correspondingly, the maximal appraisal ratio drops from 14.01 in the first subperiod to 1.48 in the last subperiod. The decline of the implied volatility relative to the physical volatility might have contributed to the weaker performance of the BXM during the last two subperiods. Possibly the decline in the difference between implied and actual volatility reflects the entry of arbitragers who sought to profit from this difference.

5. Exposure-switching strategies

The standard approach to performance evaluation entails the estimation of the regressions of the managed portfolio's excess returns on the benchmark excess returns. Can time- and performance-dependent variation in the exposure of the managed portfolio to the benchmark enhance estimated performance? A desired property of a performance estimation procedure is that if

benchmark returns are not predictable, then switching exposure between periods should not generate an alpha.

An exposure-switching managed portfolio policy could lead to a biased estimation of the portfolio's risk (beta), which in turn renders the regression misspecified. A misspecification of the regression can lead to a positive estimate of the regression's intercept, which even in the absence of the ability to trade in anticipation of future returns would lead to the false inference that the portfolio manager has superior performance.

In a simulation, Goetzmann, Ingersoll, Spiegel, and Welch (2007) report that switching exposure to a single-index benchmark can generate an alpha although the benchmark returns are identically and independently distributed (IID). Under the assumption of IID returns, this section establishes a limit on the ability to bolster the fund performance by switching benchmark exposure between observation periods. Two cases are considered in this section. In the first case the observation interval is fixed (e.g., a month), and the number of observations is very large, implying a very long time horizon T. It is shown that switching risk exposure results in a lower appraisal ratio than the maximal one covered in Theorem 1. In the second case the time horizon T is fixed but the observation interval Δt is very small. It is shown that alpha generated by switching risk exposure deteriorates as the time horizon T gets longer.

5.1. With fixed observation interval

Consider a fund manager seeking to enhance the performance of a trading strategy by cleverly changing benchmark exposures over time. Let r_{mi} be the excess benchmark return during the time period $[(i-1)\Delta t, i\Delta t]$, with mean η and variance δ^2. The sequence $\{r_{mi}\}_{i=1,\ldots,n}$ is assumed IID, i.e., the terms in the sequence have identical and independent distributions. Let r_{zi} be the excess return of any payoff $z \in X_a$ for the time period $[(i-1)\Delta t, i\Delta t]$. Assume that the sequence $\{r_{zi}\}_{i=1,\ldots,n}$ is also IID and, without loss of generality, that the excess return r_{zi} is uncorrelated with the benchmark returns. Denote the mean of r_{zi} by a and its variance by h^2. Consequently, the appraisal ratio of this strategy is a/h and, by Theorem 1 is no greater than $\text{APR}_{\max}$.

Suppose the fund manager attempts to further enhance the appraisal ratio of the strategy z by combining it with a strategy with time- and performance-dependent exposure to the benchmark. The total excess return of the fund takes the form of $r_{xi} = \beta_i r_{mi} + r_{zi}$, with β_i as a function of the past realizations of $\{\beta_j\}_{j=1,\ldots,i-1}$, $\{r_{mj}\}_{j=1,\ldots,i-1}$, and $\{r_{zj}\}_{j=1,\ldots,i-1}$.

With n periods of observed returns, the OLS regression of r_{xi} on r_{mi} produces an estimated alpha (denoted by $\widehat{\alpha}_n$), an estimated beta (denoted by $\widehat{\beta}_n$), and the appraisal ratio (denoted by $\widehat{\mathrm{APR}}_n$), which is the ratio of $\widehat{\alpha}_n$ to the estimated tracking error $\widehat{\sigma}_n$. Theorem 5 proves that in the long run switching benchmark exposures only increases tracking error, thereby worsening, not enhancing the appraisal ratio or the Sharpe ratio.

Theorem 5. *Assume that r_{mi} has a finite fourth moment and that $\lim_{n\to\infty}(1/n)\sum_{i=1}^{n}\beta_i^k$ exists for $k \leq 4$ and positive for $k=2,4$. Then, as n approaches to infinity, the alpha and the appraisal ratio converge, and the limits are*

$$\lim_{n\to\infty}\widehat{\alpha}_n = a \tag{43}$$

and

$$\lim_{n\to\infty}\widehat{\mathrm{APR}}_n = \frac{a}{\sqrt{\left(1+\frac{\eta^2}{\delta^2}\right)(h^2+\rho(\eta^2+\delta^2))}}, \tag{44}$$

where ρ is given as

$$\rho = \lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}(\beta_i - \overline{\beta}_n)^2 \quad \text{with } \overline{\beta}_n = \frac{1}{n}\sum_{i=1}^{n}\beta_i. \tag{45}$$

The theorem implies that $\lim\widehat{\mathrm{APR}}_n < a/h$, where a/h is the appraisal ratio of the payoff z. This inequality shows that it is impossible to improve long-run performance by switching the benchmark exposure between observation periods if each period has fixed length Δt (e.g., a month or a quarter).

5.2. With fixed time horizon

At variance with the preceding result, benchmark exposure switching can lead to positive alpha if the time horizon T is fixed and the observation interval Δt is very short, as is demonstrated in Theorem 6. Suppose the price of the benchmark asset follows a geometric Brownian motion:

$$S_t = S_0 e^{(\mu - 0.5\sigma^2)t + \sigma B_t}, \tag{46}$$

where B_t is a Brownian motion. It follows from Ito's lemma that the asset's instantaneous return, $dX_t = dS_t/S_t$, follows the diffusion process:

$$dX_t = \mu\,dt + \sigma\,dB_t. \tag{47}$$

If β_t is the benchmark exposure of the fund at time t, the instantaneous fund return satisfies

$$dY_t = \beta_t\,dX_t. \tag{48}$$

Let n be the number of times to observe the excess returns of the benchmark and the fund and $\Delta t = T/n$ be the length of time between two observations. Regression

of the observed fund return on the observed benchmark returns gives the intercept $\widehat{\alpha}_n$ and slope $\widehat{\beta}_n$. Theorem 6 shows how to choose β_t to maximize $\widehat{\alpha}_n$ asymptotically.

Theorem 6. *Consider all the strategies with benchmark exposures β_t bounded between $\beta^{\min}$ and $\beta^{\max}$. Their maximal expected asymptotic alpha is*

$$\max E\left[\lim_{n\to\infty}\widehat{\alpha}_n\right] = \sqrt{\frac{2}{9\pi T}}\sigma(\beta^{\max} - \beta^{\min}). \tag{49}$$

The maximum is achieved by a strategy that switches its benchmark exposure β_t^* between the lower and upper bounds:

$$\beta_t^* = \begin{cases} \beta^{\min} & \text{if } B_t \geq 0, \\ \beta^{\max} & \text{if } B_t < 0. \end{cases} \tag{50}$$

The strategy with the exposure β_t^* in Eq. (50) is a simple bang-bang strategy: Choose the lowest feasible exposure to the benchmark when the cumulative excess return to date is positive and the highest feasible exposure to the benchmark when the cumulative return is negative. The maximum expected asymptotic alpha in Theorem 6 is proportional to the volatility of the benchmark and the range of exposures. This is intuitive; higher volatility and a range of exposures allow a larger payoff space to be generated from dynamic strategies.

The apparent similarity of Theorems 6 and 1 notwithstanding, they are different in several ways. If the optimal strategy in Theorem 1 is achieved by delta trading, the strategy has dynamic exposure to the benchmark, similar to the strategy in Theorem 6. However, trading occurs at the same frequency of the observations in Theorem 6, whereas in Theorem 1 trading can be more frequent than observations. In addition, the observation interval Δt in Theorem 1 is fixed, whereas it shrinks to zero in Theorem 6. Moreover, the maximum expected asymptotic alpha in Theorem 6 is inversely proportional to the square root of the time horizon T. As the time horizon increases, the alpha generated by switching benchmark exposure is pushed toward zero.

A strategy similar to Theorem 6 is devised by Goetzmann, Ingersoll, Spiegel, and Welch (2007). Choosing $\mu = 10\%$, $\sigma = 20\%$, $\beta^{\min} = 0.5$, $\beta^{\max} = 1.5$, and $T = 5$ years, they report an average alpha of 2.05% in 10,000 simulation runs. The average Sharpe ratio of their dynamic strategy is 0.673, slightly larger than the Sharpe ratio of 0.6 delivered by a simple investment strategy in the benchmark. Applying the same set of parameters to the right-hand side of Eq. (49) gives

$$\max E\left[\lim_{n\to\infty}\widehat{\alpha}_n\right] = \frac{5.32\%}{\sqrt{T}} = \frac{5.32\%}{\sqrt{5}} = 2.38\%, \tag{51}$$

which is not much higher than the average alpha obtained by Goetzmann, Ingersoll, Spiegel, and Welch (2007), suggesting that their alpha is close to the maximum that can be generated by switching beta.

Although the strategy in Eq. (50) is only optimal with continuous trading, its performance with discrete trading can be easily evaluated through simulation. Another important reason to do simulation is to evaluate the risk

of the strategy in Theorem 6. Theorem 6 only demonstrates the positive expected alpha but says nothing about its uncertainty. Fig. 5 presents the simulation of the optimal exposure-switching strategy.

Each point in Fig. 5 corresponds to the annualized alpha and its tracking error in one of 1,000,000 simulation runs of the optimal strategy. The average alpha of 2.33% is consistent with the 2.05% reported by Goetzmann et al. and is only slightly below the asymptotic upper bound of 2.38%, confirming that continuous-time results offer reasonable approximation for monthly observations. Therefore, exposure-switching strategies can create nontrivial alpha. In addition, a strategy can be designed that comes close to achieving the maximum alpha of the exposure-switching strategy.

The uncertainty of alpha in the strategy is clearly shown by Fig. 6. The slope of the line connecting a point to the origin is the *t*-statistics or the alpha of the corresponding simulation run. The *t*-statistic of only 13% of the runs is 1.65 or higher. Close to 15% of the alphas are negative. Thus, although the exposure-switching strategy generates positive alpha, it does not do so sufficiently often or compellingly safely.

According to Theorem 6, the asymptotic upper bound on alpha decreases with the time horizon. For example, when $T=10$, alpha should be expected to be below 5.32%/10=1.68% over average. Fig. 6 presents results of 100,000 simulations for the parameter set, except the horizon T varies from 2 to 20 years. The average alpha is sensitive to the horizon and deteriorates as the horizon gets longer. However, the fraction of negative alphas exceeds the fraction of significantly positive alphas for all horizons. Managers' often-stated mantra is that over a long run their strategies win. A manager who considers building a business around exposure-switching strategy, however,
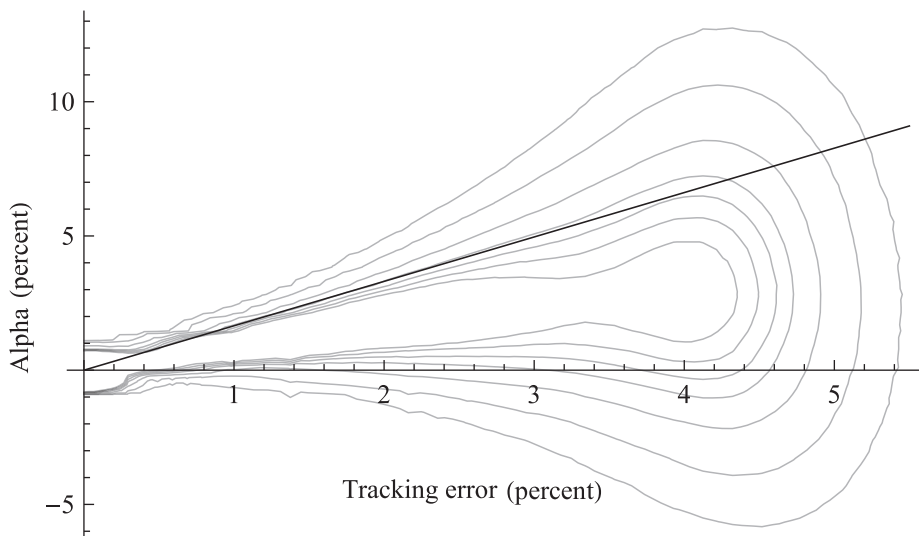

sees his results weaken over time. The enthusiasm for this strategy is tempered once one realizes that the expected fraction of negative alphas is as big as the fraction of statistically significant and positive alphas and that with longer horizons the expected alpha gets lower.
6. Concluding remarks

The maximization of alpha and the management of the associated risk are closely related to the evaluation of actively managed funds, which amounts to addressing the following question: Are the returns on the funds unusually good in comparison with those available by a portfolio of a given benchmark assets? Asset pricing theory states that if the space of payoffs spanned by the benchmark assets satisfies certain regularity conditions, then the question is equivalent to the question: Are the returns on funds unusually good by the standard of the SDF which prices all the assets in the benchmark space?

This paper's original motivation is the observation that some commonly used SDFs take on negative values in some circumstances. Thus, they could price correctly the benchmark assets but price incorrectly derivative securities on the benchmark assets, even assign them negative prices. (A simple example is a security that pays one dollar when the SDF is negative and zero otherwise. Priced by the SDF, its price must be negative, which cannot be because the security entails no liability to its holder.)

This criticism is well known for linear asset pricing models. Typically, a linear pricing model delivers period-by-period arbitrage-free pricing of existing assets (and portfolios of these assets), given the factor structure of their returns. Dybvig and Ingersoll (1982) note the possible negativity of the SDF of the CAPM and study some of

Fig. 5. Performance of optimal exposure-switching strategy. Joint distribution of the sample tracking error (*x*-axis) and the sample alpha (*y*-axis) for a portfolio that follows the strategy in Theorem 6 for five years of monthly returns. Each contour represents a level set of the joint probability density, and levels are chosen as to include (from outer to inner) 95%, 90%, 80%, 70%, 60%, 50%, and 40% of the probability. The region above the *x*-axis corresponds to positive alpha, and the region above the solid line corresponds to a statistically significant alpha (at the 5% level). Parameter values are $\mu = 10\%$, $\sigma = 20\%$, $\beta_{\min} = 0.5$, $\beta_{\max} = 1.5$, and $T=5$. The joint density is estimated by a bivariate kernel smoothing, from a simulation of 1,000,000 samples.

Fig. 6. Exposure-switching strategies as the observation period increases. The plot shows the performance of exposure-switching strategies, obtained by simulating 100,000 samples of monthly returns for each value of the observation period, which increases from 2 to 20 years. The average alpha (solid line, right scale) declines as the observation period increases, while the fractions (left scale) of negative (long dashes), significantly positive (short dashes), and insignificantly positive (dotted line) alphas remain stable. The parameters values are $\mu = 10\%$, $\sigma = 20\%$, $\beta_{min} = 0.5$, and $\beta_{max} = 1.5$.

its implications. Grinblatt and Titman (1989) point out that the nonlinear value function distorts Jensen's alpha in the CAPM. They argue that valuation models should have positive state price densities.

Trading existing assets and derivatives on them are closely related. Famously, Black and Scholes (1973) and Merton (1973) show that trading of existing securities can replicate the payoffs of options on these securities. Therefore, one should be careful in interpreting excess returns of actively managed funds estimated from linear models because such funds trade instead of hold on to the same portfolios. Examples of interpretations of asset management techniques as derivative securities include Merton (1981), who argues that market-timing strategies are akin to option trading; Fung and Hsieh (2001), who report that hedge funds using trend-following strategies behave like a look-back straddle; and Mitchell and Pulvino (2001), who report that merger arbitrage funds behave like an uncovered put.

Motivated by the challenge of evaluating rule-based trading strategies, Glosten and Jagannathan (1994) suggest replacing the linear factor models with the Black-Scholes model. Wang and Zhang (2003) study the problem extensively and develop an econometric methodology to identify the problem in factor-based asset pricing models. They show that a linear model with many factors is likely to have large pricing errors over actively managed funds, because empirically the model delivers an SDF that allows for arbitrage over derivative-like payoffs.

Lo (2001) devotes a section to dynamic risk analysis in which he offers a series of numerical examples of how a

fund can write options or equivalently trade the benchmark asset and thereby appear to have superior performance. Goetzmann, Ingersoll, Spiegel, and Welch (2007) also study the ability of money managers to manipulate performance measures, and conclude that "a manager that seeks to manipulate many of the more popular measures can indeed produce very impressive performance statistics". The results of this paper suggest otherwise.

This paper considers a general problem of performance evaluation, focusing primarily on three closely related quantities: the appraisal ratio, the improvement of the Sharpe ratio relative to the highest Sharpe ratio from a static strategy that invests only in the benchmark assets, and the reliability of the estimated alpha (its t-statistic).

At the theoretical level, the paper establishes a formula for the maximal appraisal ratio, assuming a constant investment opportunity set, and an identical investment strategy across the observation interval, which is a strategy that could include derivatives on the benchmark assets. The paper identifies the strategy that produces the maximal appraisal ratio. The formula for the maximal appraisal ratio shows the relation between the maximal improvement in the Sharpe ratio and the SDFs of the benchmark space and the larger space from which the manager picks his strategy's payoffs. The set of payoffs that delivers that maximal improvement in the Sharpe ratio is given in terms of the two SDFs.

Applying the basic result to a setup in which the benchmark asset prices follow a geometric Brownian motion with parameters matching those estimated from familiar index returns (e.g., the S&P 500 returns), a money

manager who uses options optimally only minimally enhances the measured Sharpe ratio of his fund if the options are priced according to the Black-Scholes model. Another aspect of the basic result is that the alpha generated by this manager is statistically indistinguishable from zero unless he is followed by the evaluator for many years.

Recognizing the possibility of generating positive alpha, in the absence of private information, by trading only in the benchmark assets (as often as he wishes) and derivatives on them, the paper studies the viability of such strategies by examining the maximum appraisal ratio, which measures the reward relative to the risk. Exposure-switching strategies appear more promising than those deploying options. Still, the magnitude of the generated alpha and the ratio of negative to significantly positive alphas would lead a manager away from using these techniques, even before he incorporates transactions costs into the analysis.

Options with prices that are at variance with the Black-Scholes model could open the possibility of enhancing the Sharpe and appraisal ratios. But this is due not merely to the nonlinear nature of the options payoff, but to the violation of the assumption of geometric Brownian motion, which is necessary for the validity of the Black-Scholes formula.

Appendix A

A.1. Proof of Theorem 1

As shown in Hansen and Jagannathan (1991), the stochastic discount factor m_b satisfies

$$m_b = \frac{1}{R_0} - \frac{1}{R_0} E[r_m'](\text{var}(r_m))^{-1}(r_m - E[r_m]). \tag{52}$$

It follows from Eqs. (2), (3) and (52) that the asymptotic alpha can be written as $\alpha(x) = E[r_x m_b]R_0$, which gives Eq. (7) in Theorem 1 because $E[r_x m_a] = 0$.

Being projected on r_m and $m_b - m_a$, the return r_x can be decomposed as

$$r_x = \gamma + r_m'\beta + (m_b - m_a)\theta + \varepsilon, \tag{53}$$

where ε is the residual of the projection. It follows that $E[\varepsilon] = E[(m_b - m_a)\varepsilon] = 0$ and $E[r_m\varepsilon] = 0_k$. Because $m_b - m_a$ and r_m are uncorrelated, β satisfies Eq. (3). In view of Eq. (7), the decomposition gives

$$\alpha(x) = R_0 E[(\gamma + r_m'\beta + \theta(m_b - m_a) + \varepsilon)(m_b - m_a)]$$

$$= \theta\|m_b - m_a\|^2 R_0. \tag{54}$$

Once $\|m_b - m_a\|$ is non-zero, $\alpha(x)$ is positive if, and only if, $\theta > 0$.

The decomposition in Eq. (53) also gives

$$\text{var}(r_x - r_m'\beta) = \theta^2\|m_b - m_a\|^2 + \|\varepsilon\|^2. \tag{55}$$

It then follows from Eqs. (4), (54) and (55) that the appraisal ratio is

$$\text{APR}(x) = \frac{\theta\|m_b - m_a\|^2 R_0}{\sqrt{\theta^2\|m_b - m_a\|^2 + \|\varepsilon\|^2}}. \tag{56}$$

It has an upper bound $\|m_b - m_a\|$ because

$$\frac{|\theta| \cdot \|m_b - m_a\|^2 R_0}{\sqrt{\theta^2\|m_b - m_a\|^2 + \|\varepsilon\|^2}} \leq \|m_b - m_a\|R_0. \tag{57}$$

The upper bound is achieved when $\|\varepsilon\| = 0$. For any $z \in X_b$ and $\theta > 0$, the payoff $x = z + \theta(m_b - m_a)$ has zero residual in projection (53) and thus its appraisal ratio $\text{APR}(x)$ achieves the upper bound. This gives Eq. (9) in Theorem 1. It follows that $\max\{\text{APR}(x) : x \in X_a\} = \|m_b - m_a\|R_0$, which is Eq. (8) in Theorem 1.

A.2. Proof of Theorem 2

Under the assumption of geometric Brownian motion, the unique (and hence the smallest norm) discount factor m_a is the discounted Radon-Nikodym density of the risk-neutral probability Q with respect to the physical probability:

$$m_a = e^{-[r + 0.5(\mu - r1_k)'\Sigma^{-1}(\mu - r1_k)]\Delta t - (\mu - r1_k)'\Sigma^{-1}\Delta B}, \tag{58}$$

where ΔB is the change of the Brownian motion from t to $t + \Delta t$, and 1_k is a k-dimensional vector with all components equal to one (see Karatzas and Shreve, 1998, Section 1.5). Eq. (58) is the key to the solution of the fund manager's maximization problem. With this equation, the variance of the stochastic discount factor is calculated as

$$\text{var}(m_a) = e^{-2r\Delta t}(e^{(\mu - r1_k)'\Sigma^{-1}(\mu - r1_k)\Delta t} - 1). \tag{59}$$

A substitution this equation into (14) implies that the Sharpe ratio of X_a is

$$R_0\sqrt{\text{var}(m_a)}, \tag{60}$$

which gives Eq. (27).

A.3. Proof of Theorem 3

Under the assumption of geometric Brownian motion, the solutions to the performance maximization problem (6) are linear combinations of the benchmark payoffs and the variable $m_b - m_a$. The expression of the optimal solution can be derived in the case of a single benchmark return R_m. In this case, the stochastic discount factor is

$$m_a = e^{-[r + 0.5(\mu - r)^2/\sigma^2]\Delta t - [(\mu - r)/\sigma^2]\sigma\Delta B}$$

$$= e^{-[(\mu - r)/\sigma^2]\{[\mu - 0.5\sigma^2]\Delta t + \sigma\Delta B\} + \{-r\Delta t + 0.5(\mu - r)(\mu + r - \sigma^2)/\sigma^2\}\Delta t}. \tag{61}$$

It follows from Eqs. (22) and (61) that $m_a = f(R_m)$, where $f(R_m)$ is defined in (35). The optimal strategy also involves m_b, which must be a linear function of R_m, i.e., $m_b = a + a_m R_m$ for some constants a and a_m. It follows from Eq. (9) in Theorem 1 that the payoff in Eq. (34) is an optimal strategy to the maximization problem (6).

A.4. Proof of Theorem 4

The smallest norm discount factor m_b is given by (52) and satisfies

$$\text{var}(m_b) = e^{-2(\mu+r)\Delta t}(e^{\mu\Delta t}-e^{r\Delta t})^2(e^{\sigma^2\Delta t}-1)^{-1}. \tag{62}$$

The unique stochastic discount factor in X_a is the Radon-Nikodym density of the risk-neutral probability Q with respect to the physical probability P, divided by the safe return. The expression for the SDF is

$$m_a = \lambda^{-1}e^{-r\Delta t+0.5\psi^2-0.5\lambda^{-2}(\psi+\delta\sqrt{\Delta t})^2}, \tag{63}$$

where

$$\delta = (\mu-r)/\sigma + 0.5\sigma(\lambda^2-1). \tag{64}$$

This is also the smallest norm discount factor in X_a. The variance of m_a is finite and satisfies

$$\text{var}(m_a) = e^{-2r\Delta t}(\lambda^{-1}(2-\lambda^2)^{-1/2}e^{\delta^2\Delta t/(2-\lambda^2)}-1), \tag{65}$$

provided that $\lambda \leq \sqrt{2}$. It follows by Eq. (12) that the maximal appraisal ratio is (41).

A.5. Proof of Theorem 5

The assumption in the theorem implies the existence of number b satisfying Eq. (45),

$$\lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}\beta_i = b \tag{66}$$

and

$$\lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}\beta_i^2 = b^2+\rho. \tag{67}$$

Let $\widehat{\sigma}_n$ be the estimated tracking error, which is the product of $\sqrt{n}$ and the standard error of the estimated alpha. To prove the theorem, it is sufficient to derive

$$\lim_{n\to\infty}\widehat{\alpha}_n = a \tag{68}$$

and

$$\lim_{n\to\infty}\widehat{\sigma}_n = \left(1+\frac{\eta^2}{\delta^2}\right)(h^2+\rho(\eta^2+\delta^2)) \tag{69}$$

because Eq. (44) follows immediately from (68) and (69), because $\widehat{APR}_n = \alpha_n/\widehat{\sigma}_n$.

To show Eq. (68), the following limits are shown first:

$$\lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}r_{mi} = \eta, \tag{70}$$

$$\lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}r_{mi}^2 = \eta^2+\delta^2, \tag{71}$$

$$\lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}r_{xi} = a+b\eta, \tag{72}$$

and

$$\lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}r_{mi}r_{xi} = a\eta+b(\eta^2+\delta^2). \tag{73}$$

These equations give

$$\lim_{n\to\infty}\widehat{\beta}_n = \frac{\frac{1}{n}\sum_{i=1}^{n}r_{mi}r_{xi}-\left(\frac{1}{n}\sum_{i=1}^{n}r_{mi}\right)\left(\frac{1}{n}\sum_{i=1}^{n}r_{xi}\right)}{\frac{1}{n}\sum_{i=1}^{n}r_{mi}^2-\left(\frac{1}{n}\sum_{i=1}^{n}r_{mi}\right)^2}$$

$$= \frac{b(\eta^2+\delta^2)-\eta^2b}{\eta^2+\delta^2-\eta^2} = b. \tag{74}$$

Eq. (68) can then be obtained from Eqs. (70), (72), and (74) as

$$\lim_{n\to\infty}\widehat{\alpha}_n = \lim_{n\to\infty}\left(\frac{1}{n}\sum_{i=1}^{n}r_{xi}-\widehat{\beta}_n\frac{1}{n}\sum_{i=1}^{n}r_{mi}\right)$$

$$= (a+b\eta)-b\eta = a. \tag{75}$$

Eqs. (70) and (71) immediately follow from the law of large numbers. The derivation of Eq. (72) applies a lemma from Section 12.14 in Williams (1991), which is a version of the strong law of large numbers for martingales.

Lemma 1. *Let* $(M_n)_{n\geq 0}$ *be a square-integrable martingale, and denote by* $A_n = \sum_{i=1}^{n}E_{i-1}[(M_i-M_{i-1})^2]$. *If* $A_n\to\infty$ *almost surely, then* $M_n/A_n\to 0$ *a.s.*

To derive Eq. (72), consider

$$\frac{1}{n}\sum_{i=1}^{n}r_{xi} = \frac{1}{n}\sum_{i=1}^{n}\beta_i r_{mi} + \frac{1}{n}\sum_{i=1}^{n}r_{zi}$$

$$= \frac{1}{n}\sum_{i=1}^{n}\beta_i(r_{mi}-\eta)+\eta\frac{1}{n}\sum_{i=1}^{n}\beta_i+\frac{1}{n}\sum_{i=1}^{n}r_{zi}. \tag{76}$$

The second term converges to $b\eta$ by Eq. (66), and the last one converges to a by the law of large numbers. For the first term, observe that $M_n = \sum_{i=1}^{n}\beta_i(r_{mi}-\eta)$ is an L^2 martingale and that $A_n = \sum_{i=1}^{n}E_{i-1}[(M_i-M_{i-1})^2] = \delta^2\sum_{i=1}^{n}\beta_i^2$. Hence, the lemma implies $\lim_{n\to\infty}M_n/A_n = 0$. Because

$$\lim_{n\to\infty}\frac{M_n}{A_n} = \lim_{n\to\infty}\frac{\sum_{i=1}^{n}\beta_i(r_{mi}-\eta)}{\delta^2\sum_{i=1}^{n}\beta_i^2}$$

$$= \lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}\beta_i(r_{mi}-\eta)\lim_{n\to\infty}\frac{1}{\delta^2\frac{1}{n}\sum_{i=1}^{n}\beta_i^2}, \tag{77}$$

it follows from Eq. (67) that

$$\lim_{n\to\infty}\frac{1}{n}\sum_{i=1}^{n}\beta_i(r_{mi}-\eta) = 0. \tag{78}$$

In a similar fashion, one can obtain Eq. (73) by writing

$$\frac{1}{n}\sum_{i=1}^{n}r_{mi}r_{xi} = \frac{1}{n}\sum_{i=1}^{n}\beta_i(r_{mi}^2-E[r_{mi}^2])+(\eta^2+\delta^2)\frac{1}{n}\sum_{i=1}^{n}\beta_i$$

$$+ \frac{1}{n}\sum_{i=1}^{n}r_{mi}r_{zi}, \tag{79}$$

which employed $E[r_{mi}^2] = \eta^2+\delta^2$. The second term converges to $b(\eta^2+\delta^2)$, and the third one converges to $a\eta$ by the law of large numbers and the assumption that r_{mi} and r_{zi} are uncorrelated. The assumption of a finite fourth moment ensures that the martingale in the first term is square integrable. Thus, it converges to zero by the lemma.

Now turn to Eq. (69), which requires calculating the limit of

$$\widehat{\sigma}_n^2 = \frac{\sum_{i=1}^n (r_{xi} - \widehat{\alpha}_n - \widehat{\beta}_n r_{mi})^2}{n-2} \frac{\frac{1}{n}\sum_{i=1}^n r_{mi}^2}{\frac{1}{n}\sum_{i=1}^n r_{mi}^2 - \left(\frac{1}{n}\sum_{i=1}^n r_{mi}\right)^2}. \tag{80}$$

For the second factor, Eqs. (70) and (71) imply that

$$\lim_{n\to\infty} \frac{\frac{1}{n}\sum_{i=1}^n r_{mi}^2}{\frac{1}{n}\sum_{i=1}^n r_{mi}^2 - \left(\frac{1}{n}\sum_{i=1}^n r_{mi}\right)^2} = \left(1 + \frac{\eta^2}{\delta^2}\right). \tag{81}$$

For the sum of squared regression residuals, write

$$\frac{1}{n}\sum_{i=1}^n (r_{xi} - \widehat{\alpha}_n - \widehat{\beta}_n r_{mi})^2$$
$$= \frac{1}{n}\sum_{i=1}^n (\widehat{\alpha}_n^2 - 2\widehat{\alpha}_n r_{xi} + 2\widehat{\alpha}_n \widehat{\beta}_n r_{mi} + r_{xi}^2 + \widehat{\beta}_n^2 r_{mi}^2 - 2\widehat{\beta}_n r_{mi} r_{xi})$$
$$= \widehat{\alpha}_n^2 - 2\widehat{\alpha}_n \frac{1}{n}\sum_{i=1}^n r_{xi} + 2\widehat{\alpha}_n \widehat{\beta}_n \frac{1}{n}\sum_{i=1}^n r_{mi}$$
$$+ \widehat{\beta}_n^2 \frac{1}{n}\sum_{i=1}^n r_{mi}^2 - 2\widehat{\beta}_n \frac{1}{n}\sum_{i=1}^n r_{mi}r_{xi} + \frac{1}{n}\sum_{i=1}^n r_{xi}^2. \tag{82}$$

By the previously established limits, the first term converges to a^2, the second to $-2a(a+b\eta)$, the third to $2ab\eta$, the fourth to $b^2(\eta^2+\delta^2)$, and the fifth to $-2b(a\eta+b(\eta^2+\delta^2))$. For the sixth term, one has

$$\lim_{n\to\infty} \frac{1}{n}\sum_{i=1}^n r_{xi}^2 = a^2 + h^2 + 2ab\eta + (\eta^2+\delta^2)(\rho+b^2). \tag{83}$$

To see this, expand it as

$$\frac{1}{n}\sum_{i=1}^n r_{xi}^2 = \frac{1}{n}\sum_{i=1}^n r_{zi}^2 + 2\frac{1}{n}\sum_{i=1}^n \beta_i E[r_{mi}r_{zi}] + \frac{1}{n}\sum_{i=1}^n \beta_i^2 E[r_{mi}^2]$$
$$+ \frac{1}{n}\sum_{i=1}^n 2\beta_i(r_{mi}r_{zi} - E[r_{mi}r_{zi}]) + \frac{1}{n}\sum_{i=1}^n \beta_i^2(r_{mi}^2 - E[r_{mi}^2]). \tag{84}$$

The last two terms converge to zero by the lemma. The first term converges to a^2+h^2 by the law of large numbers. The second term converges to $b\eta a$, and the third term converges to $(\eta^2+\delta^2)(b^2+\rho)$. Summing up, it follows that

$$\lim_{n\to\infty} \frac{1}{n}\sum_{i=1}^n (r_{xi} - \alpha_n - \beta_n r_{mi})^2 = h^2 + \rho(\eta^2+\delta^2), \tag{85}$$

which gives Eq. (69).

A.6. Proof of Theorem 6

The benchmark and portfolio returns during the time interval $[(i-1)\Delta t, i\Delta t]$ are

$$x_i = \mu\Delta t + \sigma(B_{i\Delta t} - B_{(i-1)\Delta t}) \tag{86}$$

and

$$y_i = \int_{(i-1)\Delta t}^{i\Delta t} \beta_t dX_t. \tag{87}$$

The estimated beta in the OLS regression of y_i on x_i is

$$\widehat{\beta}_n = \frac{\sum_{i=1}^n x_i y_i - \left(\frac{1}{n}\sum_{i=1}^n x_i\right)\left(\sum_{i=1}^n y_i\right)}{\sum_{i=1}^n x_i^2 - \left(\frac{1}{n}\sum_{i=1}^n x_i\right)\left(\sum_{i=1}^n x_i\right)}, \tag{88}$$

and the estimated alpha is

$$\widehat{\alpha}_n = \frac{1}{n}\sum_{i=1}^n y_i - \widehat{\beta}_n \frac{1}{n}\sum_{i=1}^n x_i. \tag{89}$$

Let $\alpha_T = \lim_{n\to\infty} \widehat{\alpha}_n$ and $\beta_T = \lim_{n\to\infty} \widehat{\beta}_n$. The first task is to show

$$\widehat{\beta}_T = \frac{1}{T}\int_0^T \beta_t \, dt \tag{90}$$

and

$$\alpha_T = \frac{\sigma}{T}\left(\int_0^T \beta_t dt - B_T \widehat{\beta}_T\right). \tag{91}$$

It follows from Eqs. (86) and (87) that $\sum_{i=1}^n x_i = (1/n)(\mu T + B_T)$ and that $(1/n)\sum_{i=1}^n x_i$ converges to zero as n increases to infinity. By the same token, $\sum y_i$ converges to $\int_0^T \mu\beta_t \, dt + \int_0^T \beta_t\sigma \, dB_t$ and $(1/n)\sum_{i=1}^n y_i$ converges to zero. One also has

$$\lim_{n\to\infty} \frac{1}{n}\sum_{i=1}^n x_i^2 = \lim_{n\to\infty} \sum_{i=1}^n (\mu\Delta t + \sigma(B_{i\Delta t} - B_{(i-1)\Delta t}))^2 = \sigma^2 T \tag{92}$$

and, similarly,

$$\lim_{n\to\infty} \frac{1}{n}\sum_{i=1}^n x_i y_i = \sigma^2 \int_0^T \beta_t \, dt. \tag{93}$$

Applying these results to Eq. (88) proves Eq. (90). When $n\to\infty$, the estimated alpha in Eq. (88) gives

$$\widehat{\alpha}_T = \frac{Y_T}{T} - \widehat{\beta}_T \frac{X_T}{T} = \sigma\left(\frac{1}{T}\int_0^T \beta_t \, dB_t - \widehat{\beta}_T \frac{B_T}{T}\right), \tag{94}$$

which implies Eq. (91).

The expected alpha of a trading strategy is given by

$$E[\widehat{\alpha}_T] = -\frac{\sigma}{T^2} E\left[\int_0^T \beta_t B_T \, dt\right] = -\frac{\sigma}{T^2}\int_0^T E[\beta_t B_T] \, dt$$
$$= -\frac{\sigma}{T^2}\int_0^T E[\beta_t B_t] \, dt. \tag{95}$$

Thus, to maximize this quantity while leaving $\beta_t \in [\beta_{\min}, \beta_{\max}]$ at all times, one needs to minimize $E[\beta_t B_t]$. This is the same as $\text{cov}(\beta_t, B_t)$ because B_t has zero mean. This minimum is attained for

$$\widehat{\beta}_s = \begin{cases} \beta^{\min} & \text{if } B_s \geq 0, \\ \beta^{\max} & \text{if } B_s < 0, \end{cases} \tag{96}$$

and therefore

$$E[\beta_t B_t] = \beta^{\min} E[B_t | B_t > 0]/2 + \beta^{\max} E[B_t | B_t < 0]/2. \tag{97}$$

Because

$$E[B_t | B_t > 0] = 2\int_0^\infty u \frac{e^{-u^2/2t}}{\sqrt{2\pi t}} \, du = \sqrt{\frac{2t}{\pi}}, \tag{98}$$

it follows that

$$E[\beta_t B_t] = -(\beta^{\max} - \beta^{\min})\sqrt{\frac{t}{2\pi}} \tag{99}$$

and hence

$$E[\hat{\alpha}_T] = \frac{\sigma}{T^2}\int_0^T (\beta^{\max} - \beta^{\min})\sqrt{\frac{t}{2\pi}}\,dt = \frac{\sigma}{\sqrt{T}}(\beta^{\max} - \beta^{\min})\frac{1}{3}\sqrt{\frac{2}{\pi}}, \tag{100}$$

which proves Eq. (49).
