Dynamic Investment, Capital Structure, and Debt Overhang*

Suresh Sundaresan† and Neng Wang‡

April 6, 2007

Abstract

We model dynamic investment, financing and default decisions of a firm, which begins its life with a collection of growth options. The firm exercises them optimally over time, and finances the costs of investment by trading off tax benefits of debt with both distress costs and agency costs of debt. Conflicts of interests between equityholders and various classes of debtholders are managed through optimal choice of investment triggers, capital structure, and default triggers. We show that (i) existing debt may significantly distort investment decisions (debt overhang and risk shifting); (ii) anticipating distortions induced by debt, firms with more growth options on average have lower leverages, consistent with empirical evidence; (iii) the seniority structure of debt has significant effects on the firm’s default, leverage, and investment decisions, when existing debt is exogenously given; (iv) when future growth options are anticipated, the firm optimally chooses its initial investment and leverage decisions, which substantially mitigate the anticipated endogenous debt overhang, and make debt seniority structure much less relevant.

Keywords: Endogenous default, leverage, real options, debt overhang, debt seniority

1 Introduction

Corporations face potentially interdependent, dynamic investment and financing decisions. Corporate debt and equity are issued to finance these investment opportunities, and hence their values depend on the firm’s investment, financing and default decisions. This paper provides an analytically tractable framework to analyze dynamic corporate investment, financing, and default decisions. The firm starts as a collection of growth options and optimally exercises these growth options over time. It finances the exercising costs of these growth options by adjusting its capital structure via sequential issuances of debt and equity, and trading off tax benefits of debt against both the distress and agency costs of debt. Sequential issuances of corporate securities generate multiple classes of debt with different seniorities and credit spreads. In addition, the firm’s composition in terms of assets in place and growth options changes over time, and also its incentives to default on creditors change over time. Conflicts of interests between equityholders and debtholders arise endogenously and evolve over the life-cycle of the firm.

The conventional wisdoms of debt overhang (Myers (1977)) are that (i) the pre-existing debt discourages the firm from investing because part of the value increase from new investment accrues to existing debtholders due to the debt priority and seniority structure; and (ii) anticipating this debt overhang, the firm lowers its initial debt issuance. Hennessy (2004) studies the effect of pre-existing debt on firm’s investment by injecting a consol debt into a neoclassical inter-temporal capital accumulation model of Abel and Eberly (1994). Empirically, he finds a significant overhang effect, in that the pre-existing debt may substantially distort investment and lower firm value. We contribute to the debt overhang literature in three ways. First, we show that the pre-existing debt not only generates debt overhang (Myers (1977)), but also potentially induces excessive risk taking (Jensen and Meckling (1976)). Second, we enrich the results on debt overhang by showing that debt seniority structure plays an important role in determining investment, leverage, and firm value, when debt is exogenously specified. Finally and more importantly, we show when future growth options are anticipated, the firm optimally chooses its initial investment and capital structure decision to significantly mitigate the endogenous debt overhang. Debt seniority structure also plays a much less significant role in terms of ex ante firm value, when debt is endogenously chosen. Our results on endogenous debt overhang suggest that we shall cautiously interpret the extant debt overhang literature, which is based on the assumption that debt is exogenously

---

Our paper provides a natural bridge between structural credit risk/capital structure models, and the dynamic irreversible investment theory. We find that even for firms with only one growth option, integrating investment and financing decisions generates new insights, not captured by either the standard irreversible investment models such as McDonald and Siegel (1986), or credit risk/capital structure models such as Leland (1994). For example, Leland (1994) shows that the default threshold decreases in volatility for the standard (put) option argument in a contingent claim framework based on the standard trade-off theory of Modigliani and Miller (1963). However, the default threshold in our model may either decrease or increase in volatility. The intuition is as follows: (i) a higher volatility raises the investment threshold in our model for the standard (call option) value of waiting argument; (ii) a higher investment threshold naturally leads to a greater amount of debt issuance. That is, the firm issues more debt (but at a later time), when volatility is higher. Larger debt issuance raises the default threshold, ceteris paribus. As a result, unlike Leland (1994), we have two opposing effects of volatility on the default threshold due to endogenous investment in our model.

Now consider a firm which makes sequential investment and financing decisions. In order to sharpen our intuition, we perform our analysis in two steps. First, we analyze the impact of existing debt on future investment, leverage, and default decisions. Then, we endogenize the initial investment and leverage.

First, fix the coupon and the amount of first debt issuance. Provided that the amount of pre-existing debt for the firm is not too high, the firm rationally delays exercising its future growth option. The intuition is as follows: After collecting the proceeds from (earlier) debt issuance, the firm no longer behaves in seasoned debtholders’ interests. Equityholders and new debtholders pay for the exercising cost, but the benefits from investment first go to seasoned debtholders under the absolute priority rule (APR). This ex post wealth transfer effect discourages the firm from investing. However, once the existing debt is sufficiently high, the firm starts to take excessive risks (risk shifting) by prematurely exercising growth options.

---

2McDonald and Siegel (1985, 1986) and Brennan and Schwartz (1985) are fundamental contributions to modern real options approach to investment under uncertainty. Dixit and Pindyck (1994) is a standard textbook reference on real options approach towards investment. Abel and Eberly (1994) provide a unified framework integrating the neoclassical adjustment cost literature with the literature on irreversible investment. Grenadier (2002) shows that strategic interactions among agents may substantially erode the option value of waiting.

4By APR, we refer to the seniority structure that more seasoned debt has strict priority over the newer debt in default.
This risk shifting incentive is another widely studied form of conflicts of interests between equityholders and debtholders (Jensen and Meckling (1976)). When the firm engages in risk shifting, the seasoned debtholders bear more default risks. Intuitively, when outstanding debt is too high, equityholders are better off by unloading some credit risks to senior debtholders. Not surprisingly, we also find that financial contracting such as the debt seniority structure plays a significant role for the degrees of debt overhang and risk shifting. We show that the debt overhang distortions and risk shifting incentives are more severe under APR than under the pari passu structure, when debt is exogenously specified.

Next, we endogenize the initial investment and leverage decisions. Because the firm anticipates future conflicts of interests between debtholders and equityholders once debt is in place, the firm takes a lower leverage to finance its first growth option exercising, ceteris paribus. This provides an explanation for why firms with more growth options may take a lower leverage (Smith and Watts (1992) and Rajan and Zingales (1995)). Moreover, our model predicts that the more attractive the firm’s future growth options are, the lower the firm’s current leverage is, ceteris paribus. When the firm fully anticipates agency conflicts induced by debt, the firm manages to stay within the region of moderate levels of debt, and hence avoids ex post risk shifting in endogenous debt overhang region. Intuitively, equityholders do not want to issue too much debt in the first stage and then behave opportunistically ex post via risk shifting. Finally, we find that debt seniority structure (APR versus pari passu) has smaller effects on ex ante firm value under a wide range of specifications for various structural parameters. Intuitively, the firm may use the initial investment and leverage decisions to mitigate the anticipated conflicts between debtholders and equityholders. Our model may also be viewed as a natural extension of Black and Cox (1976), who study debt pricing with exogenously specified seniority structure for debt in a contingent claim framework. Unlike Black and Cox, our model incorporates real investment and agency theory into these structural pricing models with multiple classes of debt.

Recently, there is a growing body of literature that extends Leland (1994) to allow for strategic debt service, and dynamic capital structure decisions. Fischer, Heinkel, and Zechner (1989), Goldstein, Ju, and Leland (2001), and Strebulaev (2006) formulate dynamic leverage decisions with exogenously specified investment policies. Leary and Roberts (2005)

---

5 While we focus on the seniority of debt, there are studies which differentiate the priority structure between market debt and bank debt. For example, Hackbarth, Hennessy, and Leland (2005) study the optimal mixture and priority structure of bank and market debt using the tradeoff theory. They focus on the strategic debt service motives and do not model investment decisions.

7 Early important contributions towards building dynamic capital structure models include Kane, Marcus,
empirically find that firms rebalance their capital structure infrequently in the presence of adjustment costs. Following Leland (1994), most contingent claims models of credit risk/capital structure assume that the firm’s cash flows are exogenously given and focus on the firm’s financing and default decisions.\textsuperscript{8} Unlike these work, our model endogenizes growth option exercising decisions and induces dynamic leverage decisions via motives of financing investment.\textsuperscript{9} Titman and Tsyplakov (2005) also build a model that allows for dynamic adjustment of both investment and capital structure. Their model is based on continuous investment decisions, while our model focuses on the irreversibility of growth option exercising.\textsuperscript{10} We solve the model in closed form (up to a few nonlinear equations), while Titman and Tsyplakov (2005) have three state variables and numerically solve the decision rules. Ju and Ou-Yang (2006) show that the firm’s incentive to increase firm risk \textit{ex post} is mitigated if the firm wants to issue debt periodically. In the interest of parsimony, we abstract from stochastic interest rates.\textsuperscript{11}

Our work is closely related to Hennessy and Whited (2005, 2006). Our paper complements their analysis, in that we also study dynamic investment and optimal capital structure with tradeoff, debt overhang, and endogenous default. Our work differs from theirs in the following aspects. First, motivated by the desire to deliver a parsimonious framework to integrate dynamic investment with capital structure decisions, we derive a closed form characterization for default thresholds, investment thresholds, and optimal capital structure. In contrast, they aim to capture realism (such as tax codes, distribution policy, and wedge between internal and external financing) and focus on the model’s fit to the data. Second, we model irreversibility of investment explicitly and generate endogenous action/inaction regions for investment. In their model, real investment decisions can be continuously adjusted. Third, we assume that debt financing is accomplished through the issuance of perpetual debt as in Leland (1994) and Hennessy (2004), while they use one period debt. Finally, we focus on the effects of endogenous debt overhang and the seniority structure of debt on investment, financing, and leverage decisions.

We abstract away from other frictions that may affect capital structure and investment and McDonald (1984, 1985).\textsuperscript{8} Leland (1998) extends Leland (1994) by incorporating risk management with capital structure, and also allows the firm to engage in asset substitution by selecting volatility of the project.\textsuperscript{9} Our model ties the investment and financing adjustments to occur at the same time. This assumption is made for analytical convenience. We leave extensions to allow for separate adjustments of investment and financing for future research.\textsuperscript{10} Brennan and Schwartz (1984) is an early important contribution, which allows for the interaction between investment and financing.\textsuperscript{11} See Kim, Ramaswamy, and Sundaresan (1993), Longstaff and Schwartz (1995) and Collin-Dufresne and Goldstein (2001) for extensions of Merton (1974) to allow for stochastic interest rate and other features.
decisions, such as conflicts between managers and shareholders and costly external financing. Using the empire building/free cash flow theory of Jensen (1986), Zwiebel (1996) develops a model of dynamic capital structure in which the manager trades off the benefits from empire building with the need to ensure sufficient efficiency to avoid control challenges.\footnote{Building on Jensen (1986), Stulz (1990), and Zwiebel (1996), Morellec (2004) develops a contingent claim model with manager-shareholder conflicts and shows that this agency conflict lowers leverage ratio.} Gomes (2001) studies the investment behavior of financially constrained firms and finds that standard investment regressions may produce misleading results. Cooley and Quadrini (2001) analyze an industry dynamics model of investment where the firm faces costly external financing. In our model, securities (debt and equity) are taken as given. Recently, there is a growing interest to study dynamic capital structure as a security design problem. DeMarzo and Fishman (2005), and DeMarzo and Sannikov (2006) use recursive contracting methodology to derive optimal dynamic contracts and implement the contracts with capital structure (using credit line, long term debt and equity) in discrete time and continuous time formulations, respectively.

The remainder of the paper is organized as follows. Section 2 introduces the model setup and summarizes the results for the benchmark with equity financing. Section 3 solves for the firm’s interdependent investment, default, and leverage decisions via backward induction. Section 4 derives closed-form solutions for the investment, financing, and default decisions, and analyzes the interactions among these decision rules for firms with only one growth option. In Section 5, we first study the effects of existing debt on investment, default, and leverage decisions; and then solve for the initial investment and leverage decisions, taking into account the anticipated debt overhang problem in the future. Section 6 concludes.

2 Model setup and an all-equity benchmark

We first set up a model that allows for joint determination of sequential investment, financing, and default decisions. Second, we solve for optimal investment decisions when the firm is all equity financed. We later use this all-equity setting as a natural benchmark to assess the impact of debt financing on investment.

2.1 Setup

Assume that the firm behaves in the interests of equityholders. The firm starts with two sequentially ordered growth options with no initial assets in place. Suppose that the second growth option can only be exercised after the first asset (obtained from exercising the first growth option) is in place. That is, the second growth option may be viewed as an expansion
option once the first asset is in place. Exercising the first and the second growth option costs $I_1$ and $I_2$, respectively. At each investment time, the firm may issue a mixture of debt and equity to finance the cost of exercising the growth option. Assume that debt has a tax advantage. The firm faces a constant tax rate $\tau > 0$ on its income after servicing interest payments on debt.

The firm observes the demand shock $X$ for its product, where $X$ is given by the following geometric Brownian motion (GBM) process:

$$dX(t) = \mu X(t)dt + \sigma X(t)dW_t,$$

where $W$ is a standard Brownian motion. We may view $X$ as the price process for the good produced by the firm. Assume that the risk-free interest rate is constant and is equal to $r$. For convergence, we assume $r > \mu$. Let $\Pi_1(x)$ and $\Pi_2(x)$ denote the after-tax (all-equity-financed) values of assets in place generated from exercising the first and the second growth options, respectively. Under all-equity financing, the asset in place from exercising the $k$-th growth option is given by

$$\Pi_k(x) = \frac{1 - \tau}{r - \mu} Q_k x,$$

where $Q_k > 0$ and $k = 1, 2$. The $k$-th asset in place generates revenue at the rate of $Q_k X$, where $Q_k$ is the (constant) quantity produced from the $k$-th asset in place. There is no variable production cost, and hence $Q_k X$ is the firm’s profit rate. For analytical tractability, we have intentionally chosen to model the firm as one with two sequentially ordered growth options. While our model of the firm has a stylized capital accumulation process, it captures the repeated interactions between the firm’s investment and financing decisions.

Insert Figure 1 here.

Figure 1 describes the decision making process of the firm over its life cycle. The firm may exercise its first growth option by paying a one-time fixed cost $I_1$ at endogenously chosen time $T_1$ as in McDonald and Siegel (1986). When exercising the first growth option at $T_1$, the firm may issue a mixture of debt and equity to finance the exercising cost $I_1$. Here, we follow Leland (1994) to assume that the firm will issue debt with infinite maturity. Let $c_1$

---

$^{13}$See Abel and Eberly (2005) for a model on investment and valuation with growth options.

$^{14}$Let $W$ be a standard Brownian motion in $\mathbb{R}$ on a probability space $(\Omega, \mathcal{F}, Q)$ and fix the standard filtration $\mathcal{F}_t : t \geq 0$ of $W$. Since all securities are traded here, we directly work under the risk-neutral probability measure $Q$. That is, the stochastic process (1) is under this risk-neutral measure $Q$. Under the infinite horizon, additional technical conditions such as uniform integrability are assumed here.

$^{15}$We may extend our model to allow for multiple sequentially ordered growth options. The analysis (with multiple growth options) is essentially the same as that one here for two growth options.
denote the coupon rate on the perpetual debt. This assumption of perpetual debt simplifies the analysis substantially and does not alter the key economic insights. When the firm does well, equityholders collect all the excess cash flows after servicing the debt payments and paying taxes. On the other hand, equityholders also inject the needed funds to the firm to service the debt and pay taxes when the firm has shortfalls in earnings, provided that it is in their interests to do so. Therefore, as in Leland (1994), our model does not have a role for retained earnings.

After the first asset is in place, the firm collects the cash flows $Q_1 x$ before either exercising its (second) growth option, or exercising its (first) default option. Let $T_1^d$ and $T_2^d$ denote the endogenously chosen time for firm’s first default and the second investment, after the exercise of the first growth option ($t \geq T_1^g$). As in the standard tradeoff theory, assume that debt may potentially cause distress at default, and hence is also costly to the equityholders *ex ante*. Assume that the firm recovers a fraction of residual values from the first asset in place and also from the second (unexercised) growth option, upon default at $T_1^d$. Extending Leland (1994), we assume that the firm’s total value $V_1(\cdot)$ at the first default time $T_1^d$ is given by a fraction $(1-\alpha)$ of the sum of (i) the “un-levered” value of (first) asset in place $\Pi_1(X(T_1^g))$ and (ii) $\omega\Pi_2(X(T_1^d))$, a proxy for the unexercised (second) growth option,16 in that

$$V_1(X(T_1^d)) = (1-\alpha) \left( \Pi_1(X(T_1^g)) + \omega \Pi_2(X(T_1^d)) \right),$$

(3)

where $\Pi_1(x)$ and $\Pi_2(x)$ are given by (2), and $0 \leq \omega < 1$. As in Leland (1994), we interpret $0 \leq \alpha < 1$ as a measure of inefficiency due to default. The firm loses value because of (i) distress cost ($\alpha > 0$) and (ii) forgone tax shelters. Intuitively, the residual value from the (unexercised) growth option is lower than the (first) asset in place ($0 \leq \omega < 1$). For example, the growth option may be potentially less tangible than the asset in place, and the debtholders (upon seizing the control of the firm) can only sell the unexercised (second) growth option at a discount, compared with the first asset in place. One may argue that the inalienability of the manager’s human capital for the (second) growth option may be more significant than for the (first) asset in place. As a result, it may be harder to sell the unexercised growth option, *ceteris paribus*. Because the firm receives a scrap value $(1-\alpha)\omega\Pi_2(X(T_1^d))$ at default time $T_1^d$ without paying the cost $I_2$, we need to make sure $\omega$ is sufficiently low to ensure that the (second) growth option has a lower scrap value in default than the (first) asset in place.

If the demand shock $X$ is sufficiently high, then it is optimal for the firm to exercise its second growth option. By paying the fixed investment cost $I_2$ and exercising its second growth option at endogenously chosen time $T_2^g$, the firm generates an additional stream of

---

16We have ignored the option value of waiting to invest in this linear payoff specification. However, our key results do not hinge upon the specific formulation at the default boundary.
cash flows $Q_2X$, in addition to the stream of cash flows $Q_1X$ from the first asset in place. Therefore, the total cash flow is given by $(Q_1 + Q_2)X$, after $T_2^d$ and before the firm exercises its second default option at $T_2^d$. Let $Q = Q_1 + Q_2$. As at the first investment time $T_1^i$, the firm finances the exercising cost $I_2$, by issuing a mixture of equity and the second perpetual debt with coupon $c_2$ at the second investment time $T_2^j$. For simplicity, we assume that the firm cannot call back its first perpetual debt, when exercising its second growth option and issuing the second debt.\footnote{We will return to this point later when we discuss the callability of the first debt.}

After both assets are in place and both types of debt are issued, the firm may default at endogenously chosen time $T_2^d$, if the demand shock $X$ is sufficiently low. Let $\Pi(x)$ denote the total “un-levered” firm value (with positive tax rate $\tau$):

$$\Pi(x) = \Pi_1(x) + \Pi_2(x) = \frac{1 - \tau}{r - \mu} Qx,$$

where $Q = Q_1 + Q_2$. If the firm defaults at $T_2^d$, then the firm’s default value is given by $(1 - \alpha)\Pi(X(T_2^d))$, where $\Pi(x)$ is given by (4), and $0 \leq \alpha < 1$ is a measure of inefficiency due to default as in Leland (1994).

The long maturity of debt allows us to generate debt overhang in a convenient way (Myers (1977) and Hennessy (2004)). We leave the modeling of debt maturity for future research. Because debt is perpetual and not callable, the first debt continues to exist even after exercising the second growth option. Let $D_s^2(x)$ and $D_n^2(x)$ denote the market values of the first (seasoned) debt, and of the second debt issued at the second investment time $T_2^j$, respectively. These debt values (after the second growth option is exercised) are given by

$$D_s^2(x) = E_t^x \left[ \int_t^{T_2^d} e^{-r(s-t)} c_1 ds + e^{-r(T_2^d-t)} D_s^2(X(T_2^d)) \right], \quad T_2^j \leq t \leq T_2^d, \quad (5)$$

$$D_n^2(x) = E_t^x \left[ \int_t^{T_2^d} e^{-r(s-t)} c_2 ds + e^{-r(T_2^d-t)} D_n^2(X(T_2^d)) \right], \quad T_2^j \leq t \leq T_2^d, \quad (6)$$

where $E_t^x(\cdot)$ denote the conditional expectation at time $t$ when $X(t) = x$. The residual values of the first and second debt, $D_s^2(X(T_2^d))$ and $D_n^2(X(T_2^d))$ are given by the debt seniority structure to be discussed later. We assume that the seniority structure is always respected in distress and there is no deviation from the covenants. The majority of this paper focuses on a commonly observed seniority structure: The more seasoned debt has strict seniority over debt issued later (absolute priority rule (APR)). In Section 5, we also consider an alternative seniority structure, where all debt has equal priority regardless of the issuance date, i.e. 
pari passu. Since these two debt structures have different implications on the residual values of
debt, they also have implications on investment and financing decisions. The total market value of debt after exercising both growth options is then given by

\[ D_2(x) = D_1(x) + D_3(x). \]

Let \( D_1(x) \) denote the market value of the first debt after the first growth option is exercised, but before the second growth option or the first default option is exercised. We have

\[
D_1(x) = E_t^x \left[ \int_{T_1^d \wedge T_2^d} e^{-r(s-t)} c_1 ds + e^{-r(T_1^d - t)} D_1(X(T_1^d)) 1_{T_1^d < T_2^d} + e^{-r(T_2^d - t)} D_2(X(T_2^d)) 1_{T_1^d > T_2^d} \right].
\]  

Before delving into the details on the interactions between sequential investment and financing, we first propose a benchmark, where the firm is all equity financed.

### 2.2 Benchmark: All equity financing

By definition, there is no debt \((c_1 = c_2 = 0)\) under all equity financing. Since the firm’s demand shock follows a GBM process (1) and has no variable production cost, the firm never liquidates. The firm chooses its first investment time \(T_1^i\), and its second investment time \(T_2^i \geq T_1^i\) to maximize its value given below:

\[
E^x \left[ \int_{T_1^i}^{\infty} e^{-r s} (1 - \tau) Q_1 X(s) ds - e^{-r T_1^i} I_1 + \int_{T_2^i}^{\infty} e^{-r s} (1 - \tau) Q_2 X(s) ds - e^{-r T_2^i} I_2 \right].
\]  

Throughout the paper, we will focus on the parameter regions under which the firm finds optimal to exercise the growth options sequentially. Under all equity financing, the following condition ensures that sequential exercising of the growth options is optimal.

**Condition 1** Investment benefits and costs satisfy the following inequality:

\[
\frac{Q_2}{I_2} < \frac{Q_1}{I_1}.
\]  

The above condition gives a notion for decreasing returns to scale (Grenadier (1996)). Intuitively, the second growth option is less attractive than the first growth option, when the cash flow multiple \(Q_2\) scaled by the investment cost \(I_2\) is lower than \(Q_1/I_1\). Naturally, the option value of waiting remains strictly positive after the firm exercises the first growth option.

Let \( E_0(x) \) denote the equity value before exercising the first growth option \((t \leq T_1^i)\). Let \( E_1(x) \) denote the equity value before exercising the second growth option but after exercising the first growth option \((T_1^i \leq t \leq T_2^i)\). The following proposition summarizes the known results when the firm is all equity financed and is subject to a corporate tax at rate \(\tau\).

**Proposition 1** The investment decisions under all equity financing are characterized by the threshold strategies: \(T_1^i = \inf\{t \geq 0 : X(t) = x_1^i\}\) and \(T_2^i = \inf\{t \geq 0 : X(t) = x_2^i\}\). Under Condition 1, we have \(x_1^i = x_1^{ae}\) and \(x_2^i = x_2^{ae}\), where

\[
x_k^{ae} = \frac{1}{1 - \tau} \frac{r - \mu}{\beta - 1} I_k, \quad k = 1, 2,
\]  

9
and $\beta > 1$ is given by

$$\beta = \frac{1}{\sigma^2} \left[ -\left( \mu - \frac{\sigma^2}{2} \right) + \sqrt{\left( \mu - \frac{\sigma^2}{2} \right)^2 + 2r\sigma^2} \right].$$  \hfill (11)$$

Equity values $E_0(x)$ and $E_1(x)$ are given in Appendix A.1.

When Condition 1 holds, it is optimal for the firm to sequentially exercise its two growth options. Intuitively, the exercising decisions for the two growth options are effectively independent. That is, both $x_1^i$ and $x_2^i$ are equal to the respective threshold in a setting with only one growth option (and the same set of parameters). We may strengthen our intuition for this result by noting that the joint maximization problem given in (8) may be separated into two independent one-growth-option exercising problems with parameters $(I_k, Q_k)$, provided that Condition 1 holds. Intuitively, the technological constraint that the second growth option can only be exercised after the first growth option is exercised ($T_2^i \geq T_1^i$), is not binding.

Second, taxes lower the benefits from investing under all equity financing. This explains the factor $1/(1 - \tau)$ for the investment thresholds $x_1^i$ and $x_2^i$ given in (10). Finally, both $x_1^i$ and $x_2^i$ increase in volatility, as in standard real options model such as those of McDonald and Siegel (1986).

When Condition 1 does not hold, in that $Q_1/I_1 \leq Q_2/I_2$, simultaneous exercising of both growth options is optimal. Intuitively, the second growth option is immediately worth exercising after the exercise of the first growth option. The firm rationally chooses the optimal exercising strategy by treating the two sequentially ordered growth options as a combined growth option with exercise cost $I = I_1 + I_2$, and $Q = Q_1 + Q_2$. The optimal investment threshold is then given by $x_1^* = x_2^* = x^{ae}$, where $x^{ae}$ is given by (10), with the exercising cost $I = I_1 + I_2$ and $Q = Q_1 + Q_2$.

For future comparisons, let $x_1^*$ and $x_2^*$ denote the first and second investment threshold without taxes ($\tau = 0$) when Condition 1 holds. We have

$$x_k^* = \frac{r - \mu}{Q_k} \frac{\beta}{\beta - 1} I_k, \quad k = 1, 2.$$  \hfill (12)$$

Let $x^*$ denote the corresponding optimal investment threshold with investment cost $I$ and output parameter $Q$. For example, when Condition 1 does not hold, in that $Q_1/I_1 \leq Q_2/I_2$, simultaneous exercising of both growth options is optimal. Under such a setting, $x^*$ denote the corresponding optimal investment threshold with $I = I_1 + I_2$ and $Q = Q_1 + Q_2$.

Having described the decision making process over the life-cycle of the firm and summarized the all-equity benchmark, we now turn to the paper’s focus where the firm has two growth option exercising decisions, two default and two leverage decisions.
3 Sequential investment, default and financing

First consider the firm’s decision problem after it has exercised its second growth option \((t \geq T^d_2)\). Equityholders have incentives to default after debt is in place as in Black and Cox (1976). Equityholders choose the default time \(T^d_2\) to maximize

\[
E^x_t \left[ \int_t^{T^d_2} e^{-r(s-t)} (1 - \tau) (QX(s) - c) \, ds \right], \quad t \geq T^d_2, \tag{13}
\]

where \(Q = Q_1 + Q_2\) and \(c = c_1 + c_2\). Under the assumption that equity is junior to debt, equityholders receive nothing at default. Let \(E_2(x)\) denote equity value from the above optimization problem, and \(x^d_2\) denote the endogenous (second) default threshold.

Now consider the equityholders’ decision problem after the exercise of the first growth option \((t \geq T^d_1)\). Equityholders choose either to default in which case they receive nothing, or to exercise the second growth option. If choosing to exercise the second growth option at \(T^d_2\), they will also choose the amount of the second perpetual debt to issue.

Let \(V^n_2(x)\) denote the sum of equity value and (newly issued) debt value after \(T^d_2\), in that \(V^n_2(x) = E_2(x) + D^n_2(x)\). The net gain for equityholders is thus given by \(E_2(X(T^d_2)) - (I_2 - D^n_2(X(T^d_2))) = V^n_2(X(T^d_2)) - I_2\). Equityholders choose the first default time \(T^d_1\), the second investment time \(T^d_2\) and the coupon \(c_2\) on the second perpetual debt to maximize:

\[
E^x_t \left[ \int_t^{T^d_1 \wedge T^d_2} e^{-r(s-t)} (1 - \tau) (QX(s) - c_1) \, ds + e^{-r(T^d_1 - t)} (V^n_2(X(T^d_2)) - I_2) \mathbf{1}_{T^d_1 > T^d_2} \right]. \tag{14}
\]

Let \(E_1(x)\) denote the value function from the above optimization problem, and \(x^d_1\) and \(x^i_1\) denote the endogenous default threshold, and the investment threshold, respectively. As we naturally anticipate, the default decision (the default time \(T^d_2\) and the default threshold \(x^d_2\)) solved from the last stage optimization problem (13) enters into the objective function (14) because \(V^n_2(x)\) depends on the second default threshold \(x^d_2\).

Finally, consider equityholders’ first growth option exercising decision and debt financing decision \((t \leq T^i_1)\). Since equityholders will issue debt with market value \(D_1(X(T^i_1))\) when investing, the net amount needed from equityholders will be \(I_1 - D_1(X(T^i_1))\). Note that equityholders internalize both tax benefits and the distress cost from debt issuance. They choose its first investment time \(T^i_1\) and the coupon \(c_1\) on the first debt issued at \(T^d_1\) to maximize

\[
E^x_t \left[ e^{-r(T^i_1 - t)} (V_1(X(T^i_1)) - I_1) \right], \quad t \leq T^i_1. \tag{15}
\]

where \(V_1(X(T^i_1)) = E_1(X(T^i_1)) + D_1(X(T^i_1))\). Let \(E_0(x)\) denote the equity value from the above optimization problem, and \(x^i_1\) denote the endogenous first investment threshold.
Having described the value functions in various stages, we now solve the model via backward induction. First, we solve for the default decision $x^d_2$ and value functions such as equity value $E_2(x)$ and firm value $V_2(x)$ after the second growth option is exercised ($t \geq T^*_2$).

### 3.1 After the exercise of the second growth option ($t \geq T^*_2$)

After both growth options are converted into assets in place, the firm generates total cash flows at the rate of $Qx$, where $Q = Q_1 + Q_2$. The total coupon rate is $c = c_1 + c_2$. The firm has only the default decision (characterized by the default threshold $x^d_2$) to make after both growth options are exercised. Failure to pay either debtholders immediately triggers default. Equityholders optimally choose time to default as in Leland (1994). The following value-matching and smooth-pasting conditions describe the equityholders’ optimal default decision by picking the endogenous default boundary $x^d_2$:

$$E_2(x^d_2) = 0, \quad (16)$$

$$E'_2(x^d_2) = 0. \quad (17)$$

When $x \leq x^d_2$, equity is worthless ($E_2(x) = 0$).

Leland (1994) shows that the equity value $E_2(x)$ may be written as follows:

$$E_2(x) = \Pi(x) - \frac{(1-\tau)c}{r} \left[ \Pi(x^d_2) - \frac{(1-\tau)c}{r} \right] \left( \frac{x}{x^d_2} \right)^{\gamma}, \quad x \geq x^d_2, \quad (18)$$

where the optimal default threshold $x^d_2$ is given by

$$x^d_2 = \frac{r - \mu}{Q} \frac{\gamma c}{\gamma - 1 r}, \quad (19)$$

and $\gamma$ is the negative root of the fundamental quadratic equation and is given by

$$\gamma = -\frac{1}{\sigma^2} \left[ \left( \mu - \frac{\sigma^2}{2} \right) + \sqrt{\left( \mu - \frac{\sigma^2}{2} \right)^2 + 2r\sigma^2} \right]. \quad (20)$$

Equity value $E_2(x)$ is given by (i) the “un-levered” firm value $\Pi(x)$, subtracting (ii) the present value of the tax shields $(1-\tau)c/r$, and adding (iii) the value of the default option, which is given by the product of (a) the present discounted value $(x/x^d_2)^{\gamma}$ for a unit payoff at the default boundary $x^d_2$ and (b) the present value of savings from default, $-\left( \Pi(x^d_2) - (1-\tau)c/r \right)$. At the chosen default threshold $x^d_2$ given in (19), the inequality $\Pi(x^d_2) < (1-\tau)c/r$ reflects the positive value of waiting before default. As in Black and Cox (1976) and Leland (1994), the standard option value argument implies that the default threshold $x^d_2$ decreases with volatility $\sigma$, and the equity value $E_2(x)$ is convex in $x$. 

12
We now may define various value functions, given the default threshold $x_2^d$ and the coupon rates $c_1$ and $c_2$. Before the firm defaults, equityholders make the promised payments. When the firm defaults, debt seniority structure gives the recovery values for the first and the second debt: $D_2^s(x_2^d)$ and $D_2^n(x_2^d)$. Assume that the debt covenants will be strictly enforced without any violation. Given these values at the endogenous default boundary $x_2^d$, we may write the market values of the seasoned debt issued at $T_1^i$ and of the second debt issued at $T_2^i$, before default at $T_2^d$, as follows:

\[
D_2^s(x) = \frac{c_1}{r} - \left[ \frac{c_1}{r} - D_2^s(x_2^d) \right] \left( \frac{x}{x_2^d} \right)^\gamma, \quad x \geq x_2^d,
\]

\[
D_2^n(x) = \frac{c_2}{r} - \left[ \frac{c_2}{r} - D_2^n(x_2^d) \right] \left( \frac{x}{x_2^d} \right)^\gamma, \quad x \geq x_2^d.
\]

The total debt value is $D_2(x) = D_2^s(x) + D_2^n(x)$. The total debt value at default $D_2(x_2^d)$ is equal to the total firm’s liquidation value at default, since equity is worthless at default. Using the standard argument in option pricing, we note that $D_2^s(x)$, $D_2^n(x)$, and $D_2(x)$ are all concave in $x$ because of default.

Firm value $V_2(x) = E_2(x) + D_2(x)$ is then given by

\[
V_2(x) = \Pi(x) + \frac{\tau c}{r} - \left[ \alpha \Pi(x_2^d) + \frac{\tau c}{r} \right] \left( \frac{x}{x_2^d} \right)^\gamma, \quad x \geq x_2^d.
\]

Firm value $V_2(x)$ is given by the “unlevered” (after-tax) firm value $\Pi(x)$, plus $\tau c/r$, the perpetuity value of tax shield $\tau c$ from both coupon payments $c_1$ and $c_2$ (assuming no default), minus the expected loss given default (the last term). The expected loss given default is given by the product of (i) the present discounted value $(x/x_2^d)^\gamma$ for a unit payoff at the default boundary $x_2^d$ and (ii) the loss given default $\alpha \Pi(x_2^d) + \tau c/r$, which includes both liquidation cost $\alpha \Pi(x_2^d)$ and the perpetuity value of forgone tax shields $\tau c/r$. As in Leland (1994), firm value $V_2(x)$ is concave in $x$. Intuitively, after $T_2^i$, the firm is long in the “unlevered” asset values and the tax shield perpetuity $\tau c/r$, and short in a liquidation option.

Recall that $V_2^n(x)$ is the sum of equity value $E_2(x)$ and debt value $D_2^n(x)$ issued when exercising the second growth option: $V_2^n(x) = E_2(x) + D_2^n(x)$. Using (18) and (22), we have

\[
V_2^n(x) = \Pi(x) + \frac{\tau c - c_1}{r} + \left( D_2^n(x_2^d) - \Pi(x_2^d) + \frac{c_1 - \tau c}{r} \right) \left( \frac{x}{x_2^d} \right)^\gamma, \quad x \geq x_2^d.
\]

The distinction between $V_2(x)$ and $V_2^n(x)$ is essential for our analysis. Equityholders no longer care about the payoffs to the seasoned debtholders after collecting the proceeds from the debt issuance at $T_2^i$. This creates conflicts of interests between equityholders and seasoned debtholders. Equityholders choose the investment threshold $x_2^d$ and the coupon policy $c_2$ to
maximize $V_n^2(x)$, not $V_2(x)$. The seasoned debt issued at $T^i_1$ to finance the exercise of the first growth option generates a debt overhang problem and distorts the exercising decision for the second growth option. Of course, debtholders anticipate the equityholders’ incentives and price the debt accordingly. Equityholders eventually bear the cost of this debt overhang. Unlike most papers in the literature on debt overhang, the amount of pre-existing debt and hence the severity of debt overhang in our model will be determined endogenously. We show that the significance of debt overhang is quite different, when debt is endogenously determined. Moreover, different debt seniority structure affects the debt overhang problem in different ways as we show later in Section 5.

3.2 After the exercise of the first growth option ($T^i_1 \leq t \leq T^i_2 \land T^d_1$)

When investing at the threshold $x^i_2$, equityholders need to finance the exercise cost $I_2$. Immediately after investing, the equity value is worth $E_2(x^i_2)$ after paying the part of the exercise cost $(I_2 - D_n^2(x^i_2))$ not financed by debt. The value matching condition at the investment threshold $x^i_2$ is then given by

$$E_1(x^i_2) = E_2(x^i_2) - (I_2 - D_n^2(x^i_2)) = V_n^2(x^i_2) - I_2,$$

where $V_n^2(x) = E_2(x) + D_n^2(x)$. When equityholders choose the investment threshold $x^i_2$ optimally, the following smooth pasting condition also holds:

$$E'_1(x^i_2) = V'_n(x^i_2).$$

The equityholders make the second investment decision without taking into account the interests of the seasoned debt. Therefore, $V_n^2(x^i_2)$, not $V_2(x^i_2)$, enters the right sides of the boundary conditions (25) and (26).

Now consider the coupon policy $c_2$ on the second debt issuance. The first debt issued at $T^i_1$ is already in place when the firm exercises its second growth option at $T^i_2$. Equityholders choose $c_2$ to maximize $V_n^2(x)$ and then evaluate at the investment threshold $x^i_2$. Because $x^i_2$ and $c_2$ are jointly chosen at the same time, the envelope condition ensures us that we do not need to consider the feedback effects between the endogenous investment threshold $x^i_2$ and the second coupon $c_2$. The value matching condition (25), the smooth pasting condition (26), and the fact that $c_2$ is chosen to maximize $V_n^2(x^i_2)$ rather than $V_2(x^i_2)$, all reflect the debt overhang problem.

Now turn to the (first) default option. Using the same arguments as those for the value matching and smooth pasting conditions (16) and (17) for equity value $E_2(x)$, equityholders choose the first default threshold $x^d_1$ to satisfy the value-matching condition $E_1(x^d_1) = 0$ and the smooth pasting condition $E'_1(x^d_1) = 0$. 

14
Let $\Phi_i(x)$ denote the present discounted value of receiving a unit payoff at $T_2^i$, namely, $T_2^i < T_1^i$. Similarly, let $\Phi_d(x)$ denote the present discounted value of receiving a unit payoff at $T_1^d$, namely $T_1^d < T_2$. The closed-form expressions for $\Phi_i(x)$ and $\Phi_d(x)$ are given by (A.7) and (A.8) in the appendix, respectively.\(^{18}\) Using these formulae, we may write equity value $E_1(x)$ as follows:

$$
E_1(x) = \Pi_1(x) - \frac{(1 - \tau)c_1}{r} + e^i_1\Phi_i(x) + e^d_1\Phi_d(x), \quad x_1^d \leq x \leq x_2^i, 
$$

where

$$
e^i_1 = V_2^i(x_2^i) - I_2 - \left(\Pi_1(x_2^i) - \frac{(1 - \tau)c_1}{r}\right) > 0, 
$$

$$
e^d_1 = -\left[\Pi_1(x_1^d) - \frac{(1 - \tau)c_1}{r}\right] > 0. 
$$

Equity value $E_1(x)$ is given by the sum of the “un-levered” equity value (with neither default nor growth options) and two option values: the growth option and the default option. The un-levered equity value (without growth/default options) for $E_1(x)$ is given by the difference between the un-levered value of the (first) asset in place $\Pi_1(x)$ converted from the first growth option and the perpetual value of tax shields from the first debt issuance, $(1 - \tau)c_1/r$.

The third term in (27) measures the present value of the growth option, which is given by the product of $\Phi_i(x)$, and the net payoff $e^i_1$ from exercising the option. The net payoff $e^i_1$ is the difference between the payoff from option exercise $V_2^i(x_2^i) - I_2$ and $(\Pi_1(x_2^i) - (1 - \tau)c_1/r)$, the forgone un-levered equity value when investing at the threshold $x_2^i$. Note that the forgone “un-levered” equity value appears as an additional cost term in the net payoff $e_1$ because the option payoff $V_2^i(x_2^i) - I_2$ contains cash flows from the first asset in place. Similarly, the fourth term in (27) is the present value of the default option, which is given by the product of $\Phi_d(x)$ and the net payoff $e^d_1$ upon default. Since equityholders receive nothing at default, the net payoff $e^d_1$ is given by the savings, $-\left(\Pi_1(x_1^d) - (1 - \tau)c_1/r\right) > 0$, from avoiding the loss of running the “un-levered equity value” at the default threshold $x_1^d$.

Given the default threshold $x_1^d$ and the investment threshold $x_2^i$, we may write firm value $V_1(x)$ as follows:

$$
V_1(x) = \Pi_1(x) + \frac{\tau c_1}{r} + v^i_1\Phi_i(x) + v^d_1\Phi_d(x), \quad x_1^d \leq x \leq x_2^i, 
$$

where

$$
v^i_1 = V_2(x_2^i) - I_2 - \left(\Pi_1(x_2^i) + \frac{\tau c_1}{r}\right) > 0, 
$$

$$
v^d_1 = -\left[\alpha\Pi_1(x_1^d) - (1 - \alpha)\omega\Pi_2(x_1^d) + \frac{\tau c_1}{r}\right] < 0. 
$$

\(^{18}\)Formally, $\Phi_i(x) = E^r\left[e^{-(T_2^i - t)}1_{T_2^i > T_2}\right]$, and $\Phi_d(x) = E^r\left[e^{-(T_1^d - t)}1_{T_1^d > T_2}\right]$, where $1_{T_i > T_j}$ and $1_{T_i < T_j}$ are the indicator functions. If $T_i > T_j$, we have $1_{T_i > T_j} = 1$. Otherwise, $1_{T_i > T_j} = 0$. 

15
In addition to (i) the "unlevered" (after-tax) value of the asset in place $\Pi_1(x)$ from exercising the first growth option, and (ii) the perpetuity of the tax shield $\tau c_1 / r$, firm value $V_1(x)$ also includes (iii) a long position in the growth option (the third term in (30)) and (iv) a short position in the liquidation option (the fourth term in (30)). When the firm exercises its second growth option at $T_2$, it generates a net gain $v_1^i = V_2(x_2^i) - I_2 - (\Pi_1(x_2^i) + \tau c_1 / r)$. Note that $V_2(x_2^i)$ includes the cash flows generated from the first and the second assets in place. When equityholders default at $T_1^d$, the firm loses its tax shields $\tau c_1 / r$, a fraction of unlevered value of the first asset in place $\alpha \Pi_1(x_1^d)$, but gets to recover a fraction $\omega (1 - \alpha)$ of $\Pi_2(x_1^d)$ from unexercised second growth option. Equation (32) gives $|v_1^i|$, the loss given default.

Having described the procedure to solve for the second default threshold $x_2^d$, second coupon $c_2$, the second investment threshold $x_2^i$ and the first default threshold $x_1^i$, we now turn to the investment and financing decisions for the first growth option.

### 3.3 Before the exercise of the first growth option ($t \leq T_1$)

First, consider the region where the initial value $x_0$ is sufficiently low such that it is optimal for equityholders to wait. Let $x_1^i$ denote the first endogenous investment threshold. For $x_0 \leq x_1^i$, the firm will wait until $T_1^i = \inf \{ t : X(t) \geq x_1^i \}$ to exercise the first growth option.

Equityholders internalize tax benefits, distress costs, and agency costs of debt. Thus, by exercising the first growth option, equityholders collect $E_1(x) - (I_1 - D_1(x)) = V_1(x) - I_1$. We thus have the following value matching and smooth pasting conditions:

\[
\begin{align*}
E_0(x_1^i) &= V_1(x_1^i) - I_1, \quad (33) \\
E_0'(x_1^i) &= V_1'(x_1^i). \quad (34)
\end{align*}
\]

Equity value $E_0(x)$ is then given by

\[
E_0(x) = \left( \frac{x}{x_1^i} \right)^\beta \left( V_1(x_1^i) - I_1 \right), \quad x \leq x_1^i, \quad (35)
\]

where the first investment threshold $x_1^i$ satisfies the following implicit equation:

\[
x_1^i = \frac{1}{1 - \gamma} \frac{r - \mu}{Q_1 \beta - 1} \left[ (I_1 - \frac{\tau c_1}{r}) + \frac{\beta - \gamma}{\beta \Delta} (x_1^d)^\gamma (x_1^d)^\beta v_1^i - (x_1^d)^\beta v_1^i \right], \quad (36)
\]

and $\Delta$ is a strictly positive constant given in (A.9). Unlike in the standard equity-based real options models, the payoff from investment in our model is $V_1(x)$, the sum of debt value $D_1(x)$ and equity value $E_1(x)$, which includes the present values of cash flows from both operations and financing.

Now turn to the first coupon policy $c_1$. Equityholders choose $c_1$ to maximize $E_0(x)$ and then evaluate $E_0(x)$ at $x = x_1^i$. By the value matching condition (33) and the smooth pasting
condition (34) at $x_1^i$, it is equivalent for equityholders to choose $c_1$ to maximize $V_1(x)$ and evaluate at $x_1^i$. This reflects that equityholders internalize both the tax benefits, distress and agency costs of debt when choosing $c_1$. Using the same envelope argument when we jointly choose $c_2$ and $x_2^i$, we may ignore the feedback between $c_1$ and $x_1^i$. That is, we may choose $c_1$ by plotting $V_1(x_1^i)$ for various levels of $c_1$.

So far, we have presented the solution methodology for the firm’s optimization problem, when the initial value $x_0$ is below $x_1^i$, the optimal first investment threshold. Now suppose that the initial value $x_0$ is above the optimal investment threshold $x_1^i$ from the above optimization problem ($x_0 \geq x_1^i$), then the firm shall immediately exercise its first growth option. We thus have $E_0(x_0) = V_1(x_0) - I_1$. As in earlier discussions, we will continue to use the backward induction to find optimal default thresholds $x_1^d$ and $x_2^d$, the second investment threshold $x_2^i$, and the coupon $c_2$. Equityholders then choose $c_1$ to maximize $V_1(x_0)$, taking into account the dependence of the thresholds $x_1^d$, $x_2^d$, $x_2^i$ and $c_2$ on $c_1$. If the initial value $x_0$ is really high, then the firm will find that simultaneously exercising both growth options is valuable.\(^{19}\)

### 3.4 Debt seniority structure and coupon policies

For expositional simplicity and concreteness, we assume that the first debt has seniority over the second debt, unless otherwise noted. Smith and Warner (1979) document that 90.8% of their sampled covenants contain some restrictions on future debt issuance. As in Black and Cox (1976), at default, the junior debtholders will not get paid at all until the senior debtholders are completely paid off. At the second default threshold $x_2^d$, the senior debtholders collect

$$D_2^s(x_2^d) = \min \left\{ F_1, (1 - \alpha) \Pi(x_2^d) \right\},$$

where $F_1$ is the par value of the first debt and is equal to $F_1 = D_1(x_1^i)$. The payoff function (37) states that either the senior debtholders receive $F_1$ at $T_2^d$, or the senior debtholders collect the total recovery value of the firm $(1 - \alpha) \Pi(x_2^d)$ at $T_2^d$. It is immediate to see that under this seniority structure, the junior debt value at default time $T_2^d$ is given by

$$D_2^n(x_2^d) = \max \left\{ (1 - \alpha) \Pi(x_2^d) - F_1, 0 \right\}.$$  

Let $F_2$ denote the par value of the second debt issued at $T_2^d$. The second debt is also issued at par, and thus we have $F_2 = D_2^s(x_2^d)$. Equityholders receives nothing at default, hence, we have $(1 - \alpha) \Pi(x_2^d) \leq F_1 + F_2$. Even when the senior debtholders receive par $F_1$ at default

\(^{19}\)This case is effectively one when the firm is a cash flow generating machine and effectively faces no growth option exercising decisions. The analysis is essentially Leland (1994).
time $T_d^2$, senior debtholders still prefer that the firm does not default. This is intuitive, because the par value $F_1 < c_1/r$.

Debt seniority structure matters not only for payoffs at default boundaries $x^d_2$ as in Black and Cox (1976), but also for the real investment and financial leverage decisions. The costs and benefits of issuing debt depend on the seniority and payoff structures. Moreover, the equityholders’ interests and incentives also change over time and after each financing and investment decisions. How equityholders’ incentives change over time naturally depends on the debt seniority structure.

Before studying sequential interactions among default, investment, and financing decisions, we first analyze a setting where the firm only issues one class of debt to finance the exercising cost of a single growth option. This one growth option setting provides useful insights for understanding the setting when the firm has multiple growth options.

4 Investment, default and financing: One growth option

When the firm has only one growth option, we have closed-form formulae for the joint investment, leverage, and default decisions. The explicit formulae allow us to derive sharp predictions and new important insights on interactions between investment and financing even when the firm has only one growth option, issue debt once, and has only one default option. In this section, the subscripts $k = 1, 2$ for the optimal decision rules $x^i_k$, $T^i_k$, $x^d_k$, $T^d_k$, $c_k$ all refer to the one growth option setting with corresponding investment cost $I_k$ and the cash flow multiple $Q_k$. The next proposition summarizes the main results for one growth option setting.\(^\text{20}\)

**Proposition 2** The firm’s investment decision follows a stopping time rule $T^i_k = \inf\{t : X(t) \geq x^i_k\}$, where the investment threshold $x^i_k$ is given by

$$x^i_k = \frac{\psi r - \mu}{1 - \tau} \frac{\beta}{Q_k} \frac{\beta - 1}{I_k} = \psi x^ae_k,$$

(39)

$x^ae_k$ is all-equity investment threshold given in (10), and

$$\psi = \left[ 1 + \frac{1}{h} \left( \frac{\tau}{1 - \tau} \right) \right]^{-1} \leq 1,$$

(40)

$$h = \left[ 1 - \gamma \left( 1 - \alpha + \frac{\alpha}{\tau} \right) \right]^{-1/\gamma} > 1.$$

\(^\text{20}\)Mauer and Sarkar (2005) derive similar results under one growth option setting. Their focus on the results and economic interpretations is very different. They contain operating leverage (variable production costs) and we do not. We derive explicit formulae and provide explicit link between investment and default thresholds, while they do not.
The corresponding default time $T^d_k$ is given by $T^d_k = \inf\{t > T^i_k : X(t) \leq x^d_k\}$, where the default threshold $x^d_k$ is given by $x^d_k = x^i_k/h < x^i_k$. The optimal coupon $c_k$ on the perpetual debt issued at the investment time $T^i_k$ is given by

$$c_k = \frac{r}{1-\tau} \left( \frac{\gamma - 1}{\gamma} \right) \left( \frac{\beta}{\beta - 1} \right) \left( h + \frac{\tau}{1-\tau} \right)^{-1} I_k, \quad k = 1, 2. \tag{42}$$

Equity value before investing at $T^i_k$, $E_0(x^i_k)$, is given in Appendix A.3.

Let $L_k(x)$ and $P_k(x)$ denote the debt (loan) value and firm (project) value for the setting with one growth option in order to avoid confusion with debt value $D_k(x)$ and firm value $V_k(x)$ in settings with more than one growth option. Equations (A.20) and (A.21) give the explicit formulae for $P_k(x)$ and $L_k(x)$, respectively. Note that the investment threshold $x^i_k$, the default threshold $x^d_k$, and the optimal coupon policy $c_k$ are all proportional to the investment cost $I_k$. Intuitively, if we double the investment cost $I_k$, the firm will double its investment threshold $x^i_k$, its default threshold $x^d_k$, and the optimal coupon $c_k$ accordingly. Therefore, equity value before investment $E_0(x^i_k)$, loan value $L_k(x^i_k)$, and firm (project) value $P_k(x^i_k)$ all double. This leaves leverage at the moment of investment, $L_k(x^i_k)/P_k(x^i_k)$, independent of the size of the investment cost $I_k$.

Next turn to the model’s predictions on the comparative statics of the investment threshold, the credit spread, and the default threshold, with respect to volatility.

**Proposition 3** The investment threshold $x^i_k$ given in (39), increases with volatility $\sigma$, in that $dx^i_k/d\sigma > 0$. The credit spread $cs_k$ and the ratio $h$ between the investment and the default threshold also increase with volatility $\sigma$, in that $dh/d\sigma > 0$. The default threshold $x^d_l$ may either increase or decrease in volatility $\sigma$.

First, we note that the investment threshold $x^i$ increases with volatility $\sigma$, similar to the standard real options intuition as in McDonald and Siegel (1986), which is based on all equity.

Insert Figure 2 here.

Next, turn to the effect of volatility $\sigma$ on the default threshold $x^d$. Recall that the default threshold $x^d$ in Leland (1994) decreases with volatility. The intuition is as follows. The default threshold in Leland (1994) is given by $x^d = x_0/h$, where $x_0$ is the exogenously given initial value and $h > 1$, given in (41), increases with volatility, The solid line in Figure 2 shows that the default threshold in Leland (1994) decreases with volatility, because the value of equityholders’ default option increases with volatility and hence the threshold $x^d$ decreases with volatility. Unlike Leland (1994), in our model, the default threshold $x^d_k$ may
either increase or decrease in volatility $\sigma$. The intuition is as follows. Recall that $x^d_k = x^i_k / h$, where both the numerator (the investment threshold $x^i_k$) and the denominator $h$ increase with volatility. For low levels of volatility, $x^d_k$ decreases with volatility, because the positive effect of volatility on $\log h$ is greater than the positive effect of volatility on $\log x^i_k$. For higher levels of volatility, $x^d_k$ increases with volatility, because the positive effect of volatility on the logarithmic investment threshold $\log x^i_k$ is stronger than the positive effect of volatility on $\log h$. The dashed line in Figure 2 shows the non-monotonic relationship of the default threshold $x^d$ in volatility $\sigma$.

Now turn to our model’s predictions on debt pricing. Let $c^k$ denote the credit spread: $c^k = c_k / L_k(x^i_k) - r$. Using the debt pricing formula, we have

$$c^k = r \frac{\xi}{1 - \xi}$$

where $\xi$ is given in (A.24). It is immediate to see that $c^k > 0$, because $h > 1$ and $\gamma < 0$ imply $0 < \xi < 1$. Our model generates the same prediction on the credit spread as Leland (1994) if we condition on the time of debt issuance (time 0 in Leland (1994) and the (endogenous) investment time $T^i_k$ in our model). In both models, the credit spread increases with volatility $\sigma$ for the standard option argument.

Next, we assess the impact of debt financing on ex ante firm value $E_0(x)$ and the investment decisions. The following proposition summarizes the results on the ordering of investment thresholds and also characterize the payoff functions at the moment of investment under equity financing or optimal financing. Since there is only one growth option, one default option and one financing decision, we drop the subscript for notational simplicity.

**Proposition 4** The investment threshold $x^i$ under optimal financing given in (39) is lower than $x^{ae}$ given in (10), the investment threshold under all equity financing in the presence of taxes, but is higher than $x^*$ given in (12), the investment threshold under all equity financing without taxes. That is, we have $x^{ae} > x^i > x^*$. Moreover, equity payoff values when exercising the growth option under all three scenarios are equal, in that

$$\Pi(x^{ae}) = V(x^i) = \frac{Qx^*}{r - \mu}.$$  

First, consider the impact of financing on the investment threshold. Debt provides tax benefits but induces distress costs. Positive debt issuance implies that tax benefits outweigh financial distress costs ex ante, as in standard trade-off models. Hence, the firm is more valuable under debt financing than under all equity financing. Since the payoff is higher under debt financing, the firm has greater incentives to invest ceteris paribus, which in turn implies that the investment threshold $x^i$ is lower than the threshold $x^{ae}$ under all-equity.
financing with taxes. Second, we show that the firm’s payoff from investment (even under debt financing) is lower when the tax rate is positive, compared with the case without taxes. Therefore, the firm has weaker incentives to invest, relative to the case where the firm faces no taxes, and thus the investment threshold \( x^i \) under debt financing is lower than the the optimal threshold \( x^* \) under all-equity financing without taxes.

Insert Figure 3 here.

Next, turn to the payoff values for equityholders when the firm exercises its growth options. Recall that the investment timing decisions are different under different forms of financing as discussed earlier. However, the payoffs to equityholders are all equal, if evaluated at respective growth option exercising times \( T^i \) for both all equity financing (with or without taxes) and optimal financing. Our intuition relies on the following observation. First, the present discounted value of receiving a unit payoff contingent on hitting the investment threshold \( x^i \) is \( \Phi_i(x; x^i) = \left( x/x^i \right)^{\beta} \) for \( x < x^i \) because \( x^\delta = 0 \), where \( x \) is the current value of the demand shock. It is immediate to see that \( \Phi_i(px; px^i) = \Phi_i(x; x^i) \) for any constant \( p > 0 \). Therefore, as long as the gross payoff upon exercising the growth option at the threshold level \( x^i \) is proportional to \( x^i \), say, \( px^i \), the optimal investment threshold is given by \( px^i = \beta/ (\beta - 1) I \) as shown in Appendix A.5. This relies on the scale-invariance property of \( \Phi_i(x; x^i) \) for the GBM process (1).

Figure 3 illustrates the predictions of the above proposition. We see that the three thresholds, \( x^*_1 \), \( x^i_1 \), and \( x^ae_1 \) are ordered sequentially from the left to the right. The payoff values to equityholders at these investment thresholds are equal, as seen from the (dashed) horizontal line. It is immediate to see from Figure 3 that \( \Pi(x) < V(x) < Qx/(r - \mu) \). First, tax benefits of debt imply \( V(x) > \Pi(x) \). However, taxes in net lower firm value, because forgone revenues are greater than the net tax benefits of debt in excess of financial distress costs in our model. This gives \( V(x) < Qx/(r - \mu) \). Recall that the net payoff function from exercising the option is \( V(x) - I \), which is concave in \( x \). The concavity of \( V(x) \) arises from the fact that the firm as a whole is short a default option \textit{ex ante}. Like in standard real option models, equity value \( E_0(x) \) before exercising the growth option is increasing and convex in \( x \).

Next, we analyze the feedback effects between investment and financing when the firm has two growth options. Importantly, future growth option exercising and current default decision become intertwined.
5 Model Analysis

Recall that when the firm has two growth options, we need to solve for six decision variables: two investment, two leverage, and two default decisions. In order to sharpen the intuition behind the working mechanism of our model, we first consider a simplified problem. Imagine a new manager is just hired to run the firm. He finds that the firm has existing perpetual debt with coupon $c_1$ and face value $F_1$ from the investment and leverage decisions made in the past. Behaving in equityholders’ interests, he has four decisions to make: the default decisions $(x_1^d, x_2^d)$, the investment threshold $x_2^i$, and the second coupon policy $c_2$. Without loss of generality, let the face value $F_1$ be a fraction of the corresponding risk-free debt value $c_1/r$, in that $F_1 = mc_1/r$, where the ex ante default risk of the debt implies $m < 1$.

The newly hired manager takes the first debt as given, and analyzes his optimization problem in three steps. Section 5.1 solves the special case without pre-existing debt ($c_1 = 0$) in closed form. This case has no debt induced agency conflicts and gives us a natural benchmark to analyze the effect of existing debt on future decisions and value functions. Section 5.2 analyzes the impact of pre-existing debt on firm’s default, growth option exercising, and leverage decisions, when the amount of existing debt is moderate. Section 5.3 shows that when the amount of existing debt is sufficiently large, risk shifting incentives as in Jensen and Meckling (1976) in addition to debt overhang may arise.

Having understood the simplified problem, we now endogenize the firm’s initial investment and leverage decisions. In Section 5.4, we choose the initial investment and leverage decisions, when the firm anticipates conflicts of interests after the debt is in place. Finally, we study the effect of alternative debt seniority structure on investment, financing decisions and value functions in Section 5.5.

First, consider the special case without pre-existing debt ($c_1 = 0$).

5.1 First asset in place with no debt overhang: $c_1 = 0$

When $c_1 = 0$, the firm has the first asset in place generating a perpetual (stochastic) stream of positive cash flows $Q_1x$, and the (second) unexercised growth option. Therefore, the firm never defaults before exercising the growth option ($T_1^d = \infty$). We may derive closed form solutions for value functions, and the decision rules $x_1^d$, $x_2^i$, $x_2^d$, and $c_2$. The following proposition states the main results.

Proposition 5 The firm’s optimal investment decision follows a stopping time rule $T_2^i =
\[ \inf\{ t : X(t) \geq x^i_2 \} \text{, where the investment threshold } x^i_2 \text{ is given by} \]
\[ x^i_2 = \frac{1}{1 - \tau} \frac{r - \mu}{Q_2} \frac{\beta}{\beta - 1} I_2 \left( 1 + \frac{\tau}{1 - \tau} \frac{Q}{Q_2} \right)^{-1}. \]

The optimal default time \( T^d_2 \) is given by
\[ T^d_2 = \inf \{ t > T^i_2 : X(t) \leq x^d_2 \} \text{, where the default threshold } x^d_2 \text{ is given by} \]
\[ x^d_2 = x^i_2 / h < x^i_2. \] The optimal coupon \( c_2 \) on the perpetual debt issued at the investment time \( T^i_2 \) is given by
\[ c_2 = \frac{r}{1 - \tau} \left( \frac{\gamma - 1}{\gamma} \right) \left( \frac{\beta}{\beta - 1} \right) \left( h \frac{Q^2}{Q} + \frac{\tau}{1 - \tau} \right)^{-1} I_2. \]

Equity value \( E_1(x) \) and firm value \( V_2(x) \) are given in Appendix A.6.

The firm’s investment incentive is greater than the case where the firm has only one growth option and no asset in place as in Section 4. Intuitively, the existence of the asset in place (from previous exercising of the first growth option) enhances the firm’s ability to issue debt. This additional tax benefits (netting out the financial distress cost), supported by the (first) asset in place, further encourage the firm to exercise the (second) growth option sooner, \textit{ceteris paribus}. To summarize, we have the following two results: (i) the optimal coupon \( c_2 \) given in (46) is higher than the coupon \( c_2 \) given in (42) for the case with one growth option, evaluated at investment cost \( I_2 \) and the cash flow multiple \( Q_2 \); (ii) the (second) investment threshold \( x^i_2 \) given in (45) is lower than the corresponding investment threshold \( x^i_2 \) given in (39), evaluated with investment cost \( I_2 \) and \( Q_2 \). Finally, as in one growth option setting of Section 4, the ratio between the investment threshold \( x^i_2 \) and the default threshold \( x^d_2 \) is equal to \( h \) given in (41): \( x^i_2 / x^d_2 = h \). This is an outcome from the optimal coupon and default decisions after the firm invests and issues the debt at \( T^i_2 \).

Next turn to the case where \( c_1 \) is not too high (to be made precise later). We show that the existing debt induces the classic debt overhang effect (Myers (1977)) and is reflected via default, investment and leverage decisions.

5.2 Debt overhang: “not too high” first debt coupon \( c_1 \)

By \( c_1 \) being not too high, we refer to the situation where the following condition is satisfied:

\textbf{Condition 2} \( F_1 < (1 - \alpha) \Pi(x^d_2) \).

Under the above condition, the senior debtholders receive the face value \( F_1 \) at default time \( T^d_2 \). While senior debtholders collect the par value \( F_1 \) at \( T^d_2 \), this does not mean that the senior debt has no risk after investing at \( T^i_2 \). Senior debtholders prefer a longer coupon collecting period (a higher value of \( T^d_2 \) and a lower value \( x^d_2 \)), \textit{ceteris paribus}, because of \( F_1 < c_1 / r \).
Intuitively, the senior debtholders are subject to the default timing risk. The junior debt is subject to both the risk from loss given default (compared with its par $F_2$) and the timing at which the firm defaults ($T_{d2}^q$ turns out to be too early).

Consider the effect of increasing $c_1$ on various decision rules. Start with the effect on the first default threshold $x_{d1}^q$. In the appendix, we show that

$$x_{d1}^q < \frac{\gamma}{\gamma - 1} \frac{r - \mu}{Q_1} c_1,$$

where the right side of the above inequality is the default threshold as in Leland (1994) in the absence of the second growth option. The intuition is straightforward. Because default loses future growth options and tax benefits from increasing leverage in the future, equityholders are less willing to exercise the first default option, compared with the setting without the second growth option. Note that debtholders still collect a scrap value $(1 - \alpha) \omega \Pi_2(x_{d1}^q)$ upon default from the (unexercised) second growth option, however, equityholders do not internalize this value after the first debt is issued. That is, $E_1(x)$ does not depend on the scrap value from the second growth option at default time $T_{d1}^q$. The top left panel in Figure 4 shows that for all levels of $c_1$, the default threshold $x_{d1}^q$ is below the corresponding Leland default threshold, given by the right side of (47). Also, the default threshold $x_{d1}^q$ naturally increases with $c_1$.

Next turn to the effect of $c_1$ on the (second) investment threshold $x_{i2}^q$. The seniority structure of the debt weakens equityholders’ investment incentive after the first debt is in place. This is the standard debt overhang result (Myers (1977)). Equityholders, not existing debtholders, pay the cost of exercising the second growth option by issuing securities. Given that the new debt is fairly priced, equityholders internalize the tax benefits and the distress cost from new security issuance. However, the value created from exercising the (second) growth option first goes to the senior debtholders, then new debtholders and finally equityholders. This ex post wealth transfer effect discourages equityholders from investing. Therefore, a larger $c_1$ leads to a higher investment threshold $x_{i2}^q$, ceteris paribus. The top right panel in Figure 4 shows that the second investment threshold $x_{i2}^q$ increases in $c_1$, up to a switching point, at which Condition 2 is no longer satisfied. We will return to discuss this switching point and the discontinuous downward jump of $x_{i2}^q$ in Section 5.3.

Now consider the model’s predictions after the second investment is made ($t \geq T_{i2}^q$). First, recall that equityholders’ (second) default threshold $x_{d2}^q$ as a function of the total coupon $c = c_1 + c_2$ is given by (19), the same as in Leland (1994) and in the one-growth option setting of Section 4. Taking this dependence of $x_{d2}^q$ on the total coupon $c$ into account, the firm chooses its second coupon $c_2$ (equivalently, total coupon $c = c_1 + c_2$, because $c_1$ is pre-
determined) to maximize $V_n(x_i^2)$. Using the same insight and analysis as the ones in Section 4, equityholders choose the total coupon $c$ to trade off the tax benefits with distress costs. As in Leland (1994) and Section 4, the second default threshold $x_d^2$ is proportional to the value of $x$ at which the (second) investment is taken, i.e. the investment threshold $x_i^2$. That gives $x_d^2 = x_i^2/h$, where $h$ is a constant given in (41) in Section 4. The middle left panel of Figure 4 shows that indeed the ratio $x_i^2/x_d^2$ is equal to the constant $h$, provided that $c_1$ is below the “switching” point.

More interestingly, there are two opposing effects of a higher $c_1$ on $c_2$. On one hand, fixing the level of the default threshold $x_d^2$, a unit increase of $c_1$ crowds out a unit of $c_2$. On the other hand, the investment threshold $x_i^2$ and the default threshold $x_d^2$ both increase with $c_1$ due to the debt overhang argument. Hence, the net impact of $c_1$ increase on $c_2$ is ambiguous.

Next, consider the impact of increasing $c_1$ on the credit spreads at the second investment time $T_i^2$. The credit spread at $T_2^i$ for the first debt is constant and independent of $c_1$. Intuitively, there is no loss given default for the first debt under Condition 2 (The senior debtholders receive the par value $F_1$ at default time $T_d^2$). Moreover, the ratio between the second investment threshold and second default threshold, $x_i^2/x_d^2$, is constant and equal to $h$. Hence, the credit spread at $T_2^i$ for the first debt reflects only the risk due to the stochastic default timing, which ex ante is captured by $x_i^2/x_d^2 = h$. Using the same insight as in the one growth option setting of Section 4, we know that the credit spread of the first debt at $T_2^i$ is independent of the level of $c_1$. Because the junior debt bears all the residual risk from loss given default at $T_2^d$, a higher coupon $c_1$ induces a higher loss given default for junior debt, ceteris paribus. Intuitively, a higher $c_1$ increases the risk, but is only reflected in the credit spread of the junior debt, provided that Condition 2 is satisfied. The bottom left panel of Figure 4 illustrates the impact on debt overhang on credit spreads for the first and the second debt at the firm’s second growth option exercising time $T_2^i$.

Finally, turn to the total market leverage at $T_2^i$. Building on the insights from the one growth option setting of Section 4 and also from the setting with one growth option/one asset in place and no debt of Section 5.1, we find that the market leverage at $T_2^i$ is constant and independent of $c_1$, provided that Condition 2 is satisfied. Intuitively, conditioning on investing at $T_2^i$, the existing debt $c_1$ crowds out debt capacity for the second issuance, but the total market leverage at $T_2^i$ is equal to the setting with one growth option setting, which is independent of the coupon level $c_1$. The bottom right panel of Figure 4 shows that market leverage at $T_2^i$ is independent of $c_1$, for $c_1$ lower than the switching point.

Insert Figure 4 here.
We have assumed that the outstanding debt is not too high. Intuitively, equityholders react to the debt overhang problem by postponing the second investment (by increasing the threshold $x^i_2$), and deferring the default decision (by decreasing the threshold $x^d_2$). Conditioning on the level of $x^i_2$, the firm’s second default threshold $x^d_2$ and the second coupon $c_2$ (implied by the total coupon $c$) are effectively the same as in the one growth option setting and Leland (1994) setting, provided that Condition 2 holds. Intuitively, when the existing debt is not too high, debt overhang is not significant. Hence, the firm may simply defer the second investment decision. The senior debtholders are only exposed to the timing of default. They receive the face value $F_1$ upon default at $T^d_2$. Once the second investment is made, the total financial leverage no longer needs to deviate away from the one-growth option or Leland setting.

Next, turn to the case where $c_1$ is sufficiently high.

5.3 Debt overhang and risk shifting: High first debt coupon $c_1$

Intuitively, when $c_1$ is sufficiently high, postponing the second investment to the extent that senior debt does not face any default risk at $T^d_2$ becomes too costly from equityholders’ perspective. That is, Condition 2 no longer holds. Rather than delaying investment, servicing the senior debt, and repaying the par $F_1$ on the senior debt at $T^d_2$, equityholders may have incentives to engage in risk shifting. This is in the spirit of asset substitution argument in Jensen and Meckling (1976). The discontinuous downward jump of the investment threshold $x^i_2$ in the top right panel of Figure 4 reflects (i) the potentially discontinuous payoff structure due to the seniority structure of debt and (ii) this additional effect of risk shifting on the debt overhang argument discussed earlier. Equityholders trade off the cost of risk shifting against the excessively delayed investment from the debt overhang problem. Doing so makes the senior debtholders bear additional default risk. Now the senior debt is not only exposed to the default timing risk, but also to the risk due to loss given default at $T^d_2$. The senior debtholders collect $(1 - \alpha) \Pi(x^d_2) < F_1$ and the junior debtholders receive nothing at $T^d_2$. This is precisely when Condition 2 does not hold.

After the downward jump, the investment threshold $x^i_2$ continues to increase with the coupon level $c_1$ for the standard debt overhang argument as in the previous subsection. Finally, we emphasize that where $c_1$ is sufficiently high, equityholders have both debt overhang and risk shifting incentives. The investment threshold $x^i_2$ is chosen to reflect both the debt overhang and the risk shifting incentives. Note that the level of the investment threshold $x^i_2$ after the discontinuous downward jump is still higher than the second investment threshold $x^i_2$ when $c_1 = 0$. This reflects debt overhang.
It is worth noting that the discontinuity of the investment threshold $x^i_2$ as a function of outstanding debt coupon $c_1$ reflects the nature of the payoff structure for the senior debt under APR. That is, the senior debtholders either get paid in par, or face a loss given default at $T^d_2$. This discrete payoff reflects the incentives of equityholders and the features of the decision rules, as we have shown.

### 5.4 Initial investment and coupon policy

The analysis in previous subsections have shown that the effects of existing debt (predetermined $c_1$) on future default, investment and leverage decisions are significant. However, the firm anticipates its debt policy on its future decisions, which in turn affects its current value. We show that the effect of debt overhang is significantly mitigated when the firm anticipates the distortions of current debt issuance on future decisions. Intuitively, the firm adjusts its initial investment and leverage decisions to mitigate conflicts of interests between debtholders and equityholders in the future. Appendix A.7 provides a sketch of the solution methodology motivated by economic insights behind the model.

One immediate prediction is that the firm with more growth options has a lower leverage, which is a robust empirical finding in the capital structure literature (Smith and Watts (1992) and Rajan and Zingales (1995)). The left panel of Figure 5 shows that for all levels of the exercising cost $I_2$ for the second growth option, the market leverage at the first investment time $T^i_1$ is lower than the market leverage at the second investment time $T^i_2$. Intuitively, firms with more growth options save more debt capacity for future growth option exercising in order to mitigate the potential debt overhang effect on investment and value reduction. Second, the left panel of Figure 5 shows that the more attractive the second growth option is, (a lower $I_2$, or more intuitively, a smaller $(I_2/Q_2)/(I_1/Q_1)$), the lower the firm’s market leverage is at the first investment time $T^i_1$. Third, the left panel of Figure 5 confirms that the market leverage at the second investment time $T^i_2$ is independent of the investment cost $I_2$. This is the scale invariance property that we have seen in Section 4 for the setting with one growth option.

**Insert Figure 5 here.**

The right panel of Figure 5 compares the market leverages at $T^i_1$ and $T^i_2$ with the respective stand-alone one growth option settings. To be more precise, the solid line in the right panel of Figure 5 plots the ratio between (i) the market leverage at $T^i_1$ in our setting with two growth options, and (ii) the market leverage when the firm exercises its only growth option (with exercise cost $I_1$ and $Q_1$) in the setting with only one growth option. We show that
the ratio increases with $I_2$. This confirms our intuition that the presence of future growth options lowers current leverage. The dashed line in the right panel of Figure 5 plots the ratio between (i) the market leverage at $T_2^i$ in our setting with two growth options, and (ii) the market leverage when the firm exercises its only growth option (with exercise cost $I_2$ and $Q_2$) in the setting with only one growth option. Since there is no future growth option, the ratio is equal to unity. Intuitively, with no future debt overhang, the firm has no further incentives to deviate leverage decisions. The firm anticipates that its future investment decisions will be substantially distorted with too much debt issued at $T_2^i$. Therefore, the firm issues moderate amount of debt in order to take advantage of current tax benefits without generating too much *ex post* investment inefficiency. In equilibrium, the firm faces moderate amount of debt overhang, but no incentives to risk shift. That is, anticipating the debt overhang, the firm will position itself in the region with moderate amount of $c_1$ as in Section 5.2, and will not land itself into the region with very high $c_1$ as discussed in Section 5.3.

For all the calculations that we have run, we have always found that Condition 2 holds in equilibrium, when the firm chooses all six decision rules optimally. When the firm fully anticipates its future growth options, it uses its initial investment and leverage decisions to mitigate the debt overhang problem and to avoid the equityholders’ *ex post* risk shifting behavior. This prediction (based on the endogeneity of debt issuance) is consistent with Graham and Harvey (2001), who find little survey evidence that firms engage in risk shifting/asset substitution. Our model provides one explanation: When firms anticipate future growth options, they optimally avoid the agency cost of risk shifting by lowering the leverage. Note that firms continue to be exposed to debt overhang, which simply follow from the seniority structure of debt over equity. Because Condition 2 holds in equilibrium, the senior debtholders will always collect par $F_1$ at the (second) default time $T_2^d$. Therefore, effectively, when the equityholders invest at $T_2^i$ and issue the second perpetual debt with coupon $c_2$, the senior debt is effectively retired at the market value $\xi c_1^*/r$, where $\xi$ is given in (A.24) and $c_1^*$ is the optimal coupon on the first debt under APR. Therefore, the senior debt is effectively called back at $\xi c_1^*/r$ when investing at $T_2^i$. Because calling back debt is endogenous, it is worth noting that including call feature upon investment into debt contract does not necessarily mitigate the debt overhang problem. Although our model does not allow for callability of debt directly, the model effectively captures this callability feature of debt.

Because debt seniority structure determines the payoffs for various debtholders at default, we naturally anticipate that alternative debt seniority structure, such as *pari passu*, will have different implications on investment, leverage and default decisions. This is to which we now turn. We analyze both (i) the case with exogenously specified coupon $c_1$ and also (ii) the
case with optimal initial investment and leverage decisions.

5.5 An alternative debt seniority structure: *Pari passu*

Now suppose that debt issued at \(T_i^1\) and the one issued at \(T_i^2\) have equal priority in default at time \(T_d^2\). Debt payoffs at default \((x = x_d^2)\) are proportional to \((1 - \alpha) \Pi(x_d^2)\), the total recovery value of the firm. Since both types of debt are perpetual, the residual values at the default threshold \(x_d^2\) are thus given by

\[
D_n^2(x_d^2) = \frac{c_2}{c_1 + c_2} (1 - \alpha) \Pi(x_d^2),
\]

\(48\)

\[
D_s^2(x_d^2) = \frac{c_1}{c_1 + c_2} (1 - \alpha) \Pi(x_d^2).
\]

\(49\)

Here, we assume that the payments to debtholders are based on the debt values at the second investment time \(T_i^2\). This assumption captures the key feature of the *pari passu* structure, and substantially simplify the analysis.\(^{21}\)

Equityholders choose \(c_2\) (at \(T_i^2\)) to maximize \(V_n^2(x)\) given in (24), the sum of equity value \(E_2(x)\) and newly issued debt value \(D_n^2(x)\). The following implicit function characterizes the optimal coupon \(c_2\) for a given level of the first coupon \(c_1\):

\[
c_2 = -c_1 + \frac{r}{r - \mu} \left( \frac{\gamma - 1}{\gamma} \right) \frac{1}{h} \left[ 1 - \frac{\gamma}{\gamma - 1} \left( \frac{\tau - 1 - \gamma (1 - \alpha + \alpha/\tau)}{1 - \gamma (1 - \alpha + \alpha/\tau)} \right) c_1 \right]^{1/\gamma} Q x_i^2.
\]

\(50\)

**Insert Figure 6 here.**

Figure 6 graphs the effects of existing debt on future decisions, credit spread and market leverages. Other than the first default threshold \(x_d^1\), Figure 6 shows that decision rules, credit spreads and leverages are drastically different, depending on whether the firm has APR or *pari passu* debt structure. The impact of \(c_1\) on the (second) investment threshold \(x_i^2\) is much less significant under *pari passu* than under APR. Intuitively, the *pari passu* debt structure makes debt overhang a lesser issue for equityholders. Indeed, Myers (1977) noted that firms may mitigate the debt overhang problem by issuing secured debt, or debt with equal or more senior priority over the existing debt. This is exactly what *pari passu* seniority structure does relative to APR. However, the less distorted investment threshold decision comes at a cost of lowering the equityholders’ ability to raise debt for the first growth option exercising. This suggests that the credit spread\(^{22}\) and market leverage are higher and more sensitive to \(c_1\) under *pari passu* than under APR. The bottom panels of Figure 6 confirm this intuition.

\(^{21}\)Under this assumption, we do not need to carry the face values \(F_1\) and \(F_2\) for both classes of debt. A more realistic way to model *pari passu* seniority structure is to make the payment at default proportional to the face values \(F_1\) and \(F_2\).

\(^{22}\)In our *pari passu* structure, both the first and second debt have the same credit spread.
Having illustrated the impact of debt seniority structure on investment, default, and leverage decisions, we now turn to the impact of seniority structure on equity value. First, consider the impact on $E_1(x)$ after the first debt is in place. Table 1 shows that for various parameter regions (different drift $\mu$, volatility parameter $\sigma$, distress cost $\alpha$, and tax rate $\tau$), equity value $E_1(x)$ under APR and under pari passu are significantly different. For example, for the drift parameter $\mu$ ranging from 0 to 4%, equity value $E_1(x_0)$ under APR is about 8% to 10% lower than equity value $E_1(x_0)$ under pari passu. That is, with pre-existing debt, equityholders are significantly better off with pari passu. This is intuitive, because the equityholders are less concerned about debt overhang and hence will have relatively less distorted investment decisions. To sum up, debt seniority structure plays an important role in the firm’s real investment, leverage decisions, credit spread on corporate debt, and also equity value.

So far, we have held the initial debt, such as coupon $c_1$, fixed. We next endogenize the initial investment and leverage decisions. That is, we analyze the complete optimization problem under pari passu, which is the counterpart to the complete optimization analysis in Section 5.4 under APR. Table 2 shows that the equity value $E_0(x)$ before exercising the first growth option under pari passu is very close to the equity value $E_0(x)$ under APR. This is rather opposite to the results from Table 1, when the first debt is exogenously specified. For various ranges of the drift parameter $\mu$, distress cost $\alpha$, volatility $\sigma$, and tax rate $\tau$, these two value functions are within 2% difference. Intuitively, equityholders use the initial investment threshold $x_1$ and the initial coupon policy $c_1$ as the additional adjustment margins and substantially mitigate the agency cost of debt arising from ex post debt overhang. Therefore, financial contracting plays relatively a minor role in determining the equity value $E_0(x)$ when the firm anticipates future growth option exercising and behaves rationally.

6 Conclusions

This paper develops an analytically tractable framework for studying a firm’s joint dynamic investment, capital structure and default decisions. Since equityholders make repeated investment and financing decisions, conflicts of interests between equityholders and debtholders naturally arise and evolve over time. We show that the firm waits longer before exercising its growth option when facing pre-existing debt for the standard debt overhang argument.
as in Myers (1977). More interestingly, when outstanding debt is sufficiently high, the firm may also engage in excessive risk taking (Jensen and Meckling (1976)). Conflicts of interests are reflected in credit spreads and market leverage. Debt seniority structure potentially play an important role, when debt is exogenously given. The analysis with exogenously given debt may be suitable for settings where the firm receives new growth options unexpectedly. However, when perfectly anticipating its future growth options, the firm may use its initial investment and leverage decisions as adjustment margins to mitigate the debt overhang problem. Under this situation, debt overhang is much less significant. Naturally, the role of debt seniority structure also becomes much less relevant. Our quantitative analysis provides support for these insights.
Appendices

A  Proofs

A.1 Proof of Proposition 1

Using the standard present value formulae (e.g. Dixit and Pindyck (1994)), equityholder’s objective function (8) under all equity financing may be written as follows:

\[ E_0(x) = \left( \frac{x}{x_{ae}^1} \right)^\beta \left[ \left( \frac{1 - \tau}{r - \mu} \right) Q_1 x_{ae}^1 - I_1 \right] + \left( \frac{x}{x_{ae}^2} \right)^\beta \left[ \left( \frac{1 - \tau}{r - \mu} \right) Q_2 x_{ae}^2 - I_2 \right], \quad x \leq x_{ae}^1 \]  

(A.1)

for given \( x_{ae}^1 \) and \( x_{ae}^2 \geq x_{ae}^1 \). Equityholders choose \( x_{ae}^2 \) and \( x_{ae}^1 \) to maximize (A.1). First, suppose that the constraint \( x_{ae}^2 \geq x_{ae}^1 \) does not bind. Then, we obtain the candidate optimal thresholds \( x_{ae}^1 \) and \( x_{ae}^2 \), given by (10), and \( E_0(x) \) given below:

\[ E_0(x) = \left( \frac{x}{x_{ae}^1} \right)^\beta \left( E_1(x_{ae}^1) - I_1 \right), \quad x \leq x_{ae}^1, \]  

(A.2)

where \( E_1(x) \) given by

\[ E_1(x) = \Pi_1(x) + \left( \frac{x}{x_{ae}^2} \right)^\beta \left( \Pi_2(x_{ae}^2) - I_2 \right), \quad x \leq x_{ae}^2. \]  

(A.3)

Now check if the constraint binds. We conclude that the constraint does not bind if and only if Condition 1 holds.

When the constraint \( x_{ae}^2 \geq x_{ae}^1 \) binds, i.e. \( Q_1/I_1 < Q_2/I_2 \), we have \( x_{ae}^2 = x_{ae}^1 \). That is, simultaneous exercising of both options are optimal. We thus have

\[ x_{ae}^1 = x_{ae}^2 = \frac{1}{1 - \tau} \frac{r - \mu}{Q} \beta - 1 I, \]  

(A.4)

where \( I = I_1 + I_2 \) and \( Q = Q_1 + Q_2 \). Equity value is then given by

\[ E_0(x) = \left( \frac{x}{x_{ae}} \right)^\beta (\Pi(x) - I), \quad x \leq x_{ae}, \]  

(A.5)

and \( E_0(x) = \Pi(x) - I \), if \( x \geq x_{ae} \).

A.2 Derivation for decision rules and value functions in Section 3

We proceed our analysis in several steps as in the main text.
After the exercise of the first growth option \((t \geq T_2^d)\). We conjecture that equity value \(E_2(x)\) solves the following ordinary differential equation (ODE):

\[
rE_2(x) = (1 - \tau)(Q x - c) + \mu x E_2'(x) + \frac{\sigma^2}{2} x^2 E_2''(x), \quad x \geq x_2^d,
\]

subject to the endogenous default boundary conditions (16) and (17), and the standard no-bubble condition for \(E_2(x)\) as \(x \to \infty\). Solving this (standard) default problem gives the equity value \(E_2(x)\) given in (18) and default threshold \(x_2^d\) given in (19).

After the exercise of the second growth option \((T_1^d \leq t \leq T_2^d \land T_1^d)\). Given the first default threshold \(x_1^d\) and the second investment threshold \(x_2^d\), we may write down equity value (before exercising the second, but after exercising the first growth option) \(E_1(x)\) as in (27), using the present discounted value of receiving a unit payoff contingent on the second growth option is exercised in finite time or not, \((\Phi_1(x)\) and \(\Phi_d(x))\), respectively. (Alternatively, we may also derive \(E_1(x)\) by writing down the HJB equation with the corresponding four boundary conditions. This procedure also yields (27).)

Using the standard results on hitting time distributions for GBM processes (Harrison (1985)), we have the following explicit formulae for \(\Phi_i(x)\) and \(\Phi_d(x)\):

\[
\Phi_i(x) = E_t^x \left[ e^{-r(T_2^d-t)} \mathbf{1}_{T_1^d < T_2^d} \right] = \frac{1}{\Delta} \left[ (x_2^{d})^{\gamma} x^\beta - (x_1^{d})^{\beta} x^\gamma \right], \tag{A.7}
\]

\[
\Phi_d(x) = E_t^x \left[ e^{-r(T_2^d-t)} \mathbf{1}_{T_1^d < T_2^d} \right] = \frac{1}{\Delta} \left[ (x_2^{d})^{\beta} x^\gamma - (x_1^{d})^{\gamma} x^\beta \right]. \tag{A.8}
\]

and

\[
\Delta = (x_1^{d})^{\gamma} (x_2^{d})^{\beta} - (x_1^{d})^{\beta} (x_2^{d})^{\gamma} > 0. \tag{A.9}
\]

It is immediate to see that \(\Phi_d(x_1^d) = \Phi_i(x_2^d) = 1, \Phi_d(x_2^d) = \Phi_i(x_1^d) = 0, \) and \(\Phi_d(x) > 0, \Phi_i(x) > 0, \) for \(x_1^d < x < x_2^d\).

Using the equity value formula (27), we have \(x E_1'(x) = \Pi_1(x) + e_1^{d} \Phi_i'(x)x + e_1^{d} \Phi_d'(x)x\). The smooth pasting condition \(E_1'(x_2^d) = V_2''(x_2^d)\) implies

\[
\Pi_2(x_2^d) + \gamma \nu_2^n \left( \frac{x_2^d}{x_2^d} \right)^\gamma = \frac{\beta}{\Delta} (x_2^{d})^{\beta} \left[ e_1^{d} (x_1^{d})^{\gamma} - e_2^{d} (x_2^{d})^{\gamma} \right] - \frac{\gamma}{\Delta} (x_2^{d})^{\gamma} \left[ e_1^{d} (x_1^{d})^{\beta} - e_2^{d} (x_2^{d})^{\beta} \right], \tag{A.10}
\]

where \(\nu_2^n\) is given by

\[
\nu_2^n = D_2^n (x_2^d) - \Pi(x_2^d) + \frac{c_1 - \tau c}{r}. \tag{A.11}
\]

Similarly, the smooth pasting condition \(E_1'(x_1^d) = 0\) gives

\[
0 = \Pi_1(x_1^d) + \frac{\beta}{\Delta} (x_1^{d})^{\beta} \left[ e_1^{d} (x_1^{d})^{\gamma} - e_2^{d} (x_2^{d})^{\gamma} \right] - \frac{\gamma}{\Delta} (x_2^{d})^{\gamma} \left[ e_1^{d} (x_1^{d})^{\beta} - e_2^{d} (x_2^{d})^{\beta} \right]. \tag{A.12}
\]
For given $x_1^d$ and $x_2^i$, debt value $D_1(x)$ is then given by

$$D_1(x) = \frac{c_1}{r} + \left(D_2^i(x_2^i) - \frac{c_1}{r}\right) \Phi_i(x) + \left[(1 - \alpha) \Pi_1(x_1^d) - \frac{c_1}{r}\right] \Phi_d(x). \quad (A.13)$$

**Before the exercise of the first growth option** ($t \leq T_1^i$). We conjecture that the equity value $E_0(x)$ solves the following ODE:

$$rE_0(x) = \mu x E_0'(x) + \frac{\sigma^2}{2} x^2 E_0''(x), \quad x \leq x_1^i. \quad (A.14)$$

The above ODE is solved subject to the endogenous default boundary conditions (33) and (34) given in the main text, and also the standard absorbing barrier for $E_0(x)$ at the origin, in that as $E_0(x) \to 0$, when $x \to 0$.

Substituting the conjectured equity value (35) into the ODE (A.14) and applying the endogenous default boundary conditions (33) and (34) gives the following implicit equation for the first investment threshold $x_1^i$:

$$\Pi_1(x_1^i) = \frac{\beta}{\beta - 1} \left[I_1 - \frac{\tau c_1}{\gamma} + \frac{\Phi_i(x_1^i)}{\beta} - \frac{\beta - \gamma}{\beta} \left(\alpha \Pi_1(x_1^d) + \frac{\tau c_1}{\gamma} \left(x_1^d \right)^\gamma \right)\right]. \quad (A.15)$$

Simplifying the above gives (36).

### A.3 Proof of Proposition 2

With one growth option, we have $x_2^i = \infty$. Therefore, $\Phi_i(x) = 0$ and $\Phi_d(x) = \left(x/x_1^i\right)^\gamma$, for $x \geq x_1^i$. Equation (36) thus implies

$$x_1^i = \frac{1}{\beta - 1} \left[I_1 - \frac{\tau c_1}{\gamma} + \frac{\Phi_i(x_1^i) x_1^i - \beta \Phi_i(x_1^i)}{\beta} \right]^{\gamma}. \quad (A.16)$$

The optimal coupon policy $c$ is given by

$$c_1 = \frac{r}{r - \mu} \frac{\gamma - 1}{\gamma} x_1^i. \quad (A.17)$$

Re-arranging and simplifying (A.16) gives the following implicit equation for the investment threshold:

$$(\beta - 1) \Pi_1(x_1^i) = \beta I_1 - \beta \frac{\tau c_1}{r} + \left(\beta - \gamma\right) \frac{c_1}{r} \left[\alpha \left(1 - \tau\right) \left(\frac{\gamma}{\gamma - 1}\right) + \tau\right] h^\gamma,$$

$$= \beta I_1 - \beta \frac{\tau c_1}{r} + \left(\beta - \gamma\right) \frac{\tau c_1}{r} \left(\frac{h^\gamma}{1 - \gamma}\right) h^\gamma,$$

$$= \beta I_1 - \left(\beta - 1\right) \frac{1}{h} \frac{Q_1 x_1^i}{r - \mu} \frac{1}{h^\gamma} \frac{1}{r - \mu}, \quad (A.18)$$

where the first, second, and third line uses the explicit formulae for $x_1^d$ given in (19), $h$ given in (41), and coupon $c$ given in (A.17), respectively. Finally, re-arranging the last expression
gives $x^i_1$ in (39). Substituting (39) into (A.17) gives the coupon policy (42) and the default threshold $x^d_i = x^i_1/h$. The same naturally analysis applies when the firm has investment cost $I_2$ and the cash flow multiple $Q_2$.

If the initial value $x_0$ is below the investment threshold $x^i_k$ given in (39), the firm will wait to invest. Equity value before investment $E_0(x)$ is given by

$$E_0(x) = \left( \frac{x}{x^i_k} \right)^\beta \left( P_k(x^d_k) - I_k \right), \quad x \leq x^i_k,$$

(A.19)

where project value $P_k(x)$ after investment and before default ($T^i_k \leq t \leq T^d_k$) is given by

$$P_k(x) = \Pi_k(x) + \frac{\tau c_k}{r} - \left( \alpha \Pi_k(x^d_k) + \frac{\tau c_k}{r} \right) \left( \frac{x}{x^d_k} \right)^\gamma, \quad x \geq x^d_k.$$  

(A.20)

When $x \leq x^d_k$, project is worthless, in that $P_k(x) = 0$. The loan value $L_k(x)$ issued to finance the project is then given by

$$L_k(x) = \frac{c_k}{r} - \left[ \frac{c_k}{r} - (1 - \alpha) \Pi_k(x^d_k) \right] \left( \frac{x}{x^d_k} \right)^\gamma, \quad x \geq x^d_k.$$  

(A.21)

The difference $P_k(x) - L_k(x)$ is the residual equity value.

A.4 Proof of Proposition 3

Recall that $\Phi_d(x)$ denote the present discounted value of receiving a unit payoff contingent on the event that the process $X$ hits $x^d$, the default threshold for the firm after investing at the threshold $x^i$ at time $T^i$ (Note that the upper boundary in this case for the calculation $\Phi_d(x)$ is $\infty$). (A.8) implies $\Phi_d(x) = (x/x^d)^\gamma$ for $x \geq x^d$. Hence,

$$\Phi_d(x^i) = h^\gamma = \left[ 1 - \gamma \left( 1 - \alpha + \frac{\alpha}{\tau} \right) \right]^{-1}.$$  

(A.22)

It is immediate to see that $\Phi_d(x^i)$ increases with volatility $\sigma$, increases with tax rate $\tau$, and decreases with financial distress cost $\alpha$. Now consider the credit spread at issuance/investment time $T^i$:

$$cs = \frac{c}{L(x^i)} - r = r \frac{\xi}{1 - \xi},$$  

(A.23)

where $L(x)$ is loan value given in (A.21) and

$$\xi = \left( 1 - (1 - \alpha) (1 - \tau) \frac{\gamma}{\gamma - 1} \right) h^\gamma.$$  

(A.24)

Note $0 < \xi < 1$, because $h > 1$, $\gamma < 0$, $0 \leq \alpha < 1$, and $0 \leq \tau < 1$. We also note that $d\xi/d\sigma^2 > 0$ because $d\gamma/d\sigma^2 > 0$ and $d\Phi_d(x^i)/d\sigma^2 > 0$. Therefore, credit spread increases with volatility $\sigma$.  

35
Note that $h = (1 - \gamma B)^{-1/\gamma}$ satisfies $1 < h < e^B$, where $B = 1 + \alpha (1 - \tau) / \tau > 1$. Using the chain rule, we have

$$\frac{dh}{d\sigma^2} = \frac{dh}{d\gamma} \frac{d\gamma}{d\sigma^2} = h \frac{d\log h}{d\gamma} \frac{d\gamma}{d\sigma^2}, \quad (A.25)$$

where

$$\frac{d\log h}{d\gamma} = \frac{1}{\gamma^2} \left( \log (1 - \gamma B) + \frac{\gamma B}{1 - \gamma B} \right) = \frac{1}{\gamma^2} G(\gamma), \quad (A.26)$$

and

$$G(\gamma) = \log (1 - \gamma B) + \frac{1}{1 - \gamma B} - 1, \quad \text{for } \gamma < 0. \quad (A.27)$$

It is immediate to see that $G(0) = 0$ and $G'(\gamma) < 0$, over the region $\gamma < 0$. Therefore, we have $d\log h/d\gamma > 0$. Note that $d\gamma/d\sigma^2 > 0$. Therefore, using (A.25), we have $dh/d\sigma^2 > 0$.

The sign of $d\psi/d\sigma^2$ is the same as the sign of $dh/d\sigma^2$. We thus have $d\psi/d\sigma^2 > 0$. Since $x^i = \psi x^{ae}$, and both $\psi$ and $x^{ae}$ given in (10) increase with volatility, we thus have $dx^i/d\sigma^2 > 0$.

### A.5 Proof of Proposition 4

First, we show that as long as the (gross) payoff to equityholders when exercising the growth option at the threshold $x^i$ is proportional to $x^i$, then the payoff values when investing are identical and independent of financing arrangements. Suppose that the gross payoff when investing is given by $px$, where $p > 0$ is a constant.

Because the equity value $E_0(x)$ (for $x \leq x^i$) is given by product of (i) the present discounted value of a unit payoff at the investment threshold $x^i$, $(x/x^i)^\beta < 1$, and (ii) the net payoff at the investment threshold, $px^i - I$. Therefore, equityholders choose $x^i$ to maximize $(x/x^i)^\beta (px^i - I)$. Solving gives

$$px^i = \frac{\beta}{\beta - 1} I. \quad (A.28)$$

Therefore, equity value is given by $(x/x^i)^\beta I/ (\beta - 1)$.

Now, we show that for both equity financing and optimal financing, we have linear payoff value. Under all equity financing with taxes, the gross payoff value when investing is given by $\Pi(x^{ae}) = (1 - \tau) Qx^{ae}/(r - \mu)$. Under all equity financing without taxes, the gross payoff value when investing is given by $\Pi(x^*) = Qx^*/(r - \mu)$. Finally, under optimal financing, we have

$$V(x^i) = \Pi(x^i) + \left[ \alpha (1 - \tau) \frac{\gamma}{\gamma - 1} + \tau \right] h^\gamma \left[ \frac{\gamma - 1}{\gamma} - \frac{1}{1 - \tau h} \Pi(x^i) - \Pi(x^i) \psi, \quad (A.29) \right.$$

using expressions for $h$ given in (41), $\psi$ given in (40), $x^d$ given in (19), and $c$ given in (A.17). Note that $\Pi(x^i)$ is linear in $x^i$.
A.6 Proof of Proposition 5

Using the standard pricing argument, we have that equity value before exercising the (second) growth option, $E_1(x)$, is given by

$$E_1(x) = \Pi_1(x) + (V_2(x^i_2) - I_2) \left( \frac{x}{x^i_2} \right)^\beta, \quad x \leq x^i_2,$$

where firm value $V_2(x)$ after investment and before default ($T^i_2 \leq t \leq T^d_2$) is given by

$$V_2(x) = \Pi(x) + \frac{\tau c_2}{r} - \left[ \alpha \Pi(x^d_2) + \frac{\tau c_2}{r} \right] \left( \frac{x}{x^d_2} \right)^\gamma, \quad x \geq x^d_2. \tag{A.31}$$

The optimal coupon policy $c_2$ that maximizes $V_2(x^i_2)$ is given by

$$c_2 = \frac{r - \mu}{r - \mu - \frac{1}{h} Q x^i_2}, \tag{A.32}$$

and $x^d_2 = x^i_2/h$. Using the smooth pasting condition $E'_1(x^i_2)x^i_2 = V'_2(x^i_2)x^i_2$, we have

$$x^i_2 = \frac{1}{1 - \tau} \frac{r - \mu}{Q_2 \beta - 1} \left[ \left( I_2 - \frac{\tau c_2}{r} \right) + \frac{\beta - \gamma}{\beta} \left( \alpha \Pi(x^d_2) + \frac{\tau c_2}{r} \right) \left( \frac{x^d_2}{x^i_2} \right)^\gamma \right]. \tag{A.33}$$

Re-arranging and simplifying (A.33) gives the following implicit equation for $x^i_2$:

$$(\beta - 1) \Pi_2(x^i_2) = \beta I_2 - \beta \frac{\tau c_2}{r} + (\beta - \gamma) \frac{c_2}{r} \left[ \alpha \left( 1 - \tau \right) \left( \frac{\gamma}{\gamma - 1} \right) + \tau \right] h^\gamma,$n

$$= \beta I_2 - (\beta - 1) \tau \frac{Q x^d_2}{r - \mu} \frac{\gamma}{\gamma - 1}. \tag{A.34}$$

Using $x^d_2 = x^i_2/h$ and re-arranging the last equation gives (45).

A.7 Numerical solution methodology

We solve for the six decision rules: two investment thresholds $(x^i_1, x^i_2)$, two default thresholds $(x^d_1, x^d_2)$, and two coupons $(c_1, c_2)$ using the following procedure:

1. Fixing $c_1$, we solve for the first default threshold $x^d_1$, the second investment threshold $x^i_2$, the second coupon policy $c_2$, and the second default threshold $x^d_2$, using the following iterative procedure in order to ensure numerical accuracy.

   - Start with the case where $c_1 = 0$. We have closed form solutions for $x^i_2$, $x^d_2$, and $c_2$ (See Section 5.1).

   - Consider small $c_1 = \epsilon > 0$. Use the optimal decision rules for $(x^d_1, x^i_2, x^d_2, c_2)$ from the previous step ($c_1 = 0$) as initial guess values to solve for $(x^d_1, x^i_2, x^d_2, c_2)$, for the case with $c_1 = \epsilon > 0$. 

37
• Consider the setting with $c_1 = 2\epsilon$. Use the optimal decision rules $(x_{d1}^i, x_{i2}, x_{d2}, c_2)$ for the case with $c_1 = \epsilon$ as initial guesses to solve for the decision rules.

• Consider the setting with $c_1 = 3\epsilon$. The process continues.

2. Use the implicit equation (36) (implied by maximizing $E_0(x)$ given in (35)) to solve for the first investment trigger $x_1^i$ for given $c_1$ and the corresponding decision rules from the previous step.

3. Plot the implied equity value $E_0(x; c_1)$ with respect to $c_1$, and choose the level of $c_1$ which gives the highest value $E_0(x; c_1)$.

Figure 1: **The firm’s decision making process over its life cycle.** The firm starts with two sequentially ordered growth options. It exercises its first growth option when \( x \geq x_1^i \) and waits otherwise. When exercising, the firm issues a mixture of equity and the first perpetual debt with coupon \( c_1 \) to finance the exercising cost \( I_1 \), and generates EBIT \( Q_1 x \), provided that \( x_1^d < x < x_2^i \). When \( x \leq x_1^d \), the firm defaults. When \( x \geq x_2^i \), the firm exercises its second growth option, and issues a mixture of equity and the second perpetual debt with coupon \( c_2 \) to finance the exercising cost \( I_2 \). After both options are exercised, the firm generates EBIT \( (Q_1 + Q_2) x \), provided that \( x \geq x_2^d \). It defaults when \( x \leq x_2^d \). The six decision rules include two investment thresholds \( (x_1^i, x_2^i) \), two default thresholds \( (x_1^d, x_2^d) \), and two coupon policies \( (c_1, c_2) \).
Figure 2: Comparative statics of the default trigger $x^d$ with respect to volatility $\sigma$: Leland (1994) (with one asset in place) versus our model (with one growth option as in Section 4). The dashed line shows that the default threshold $x^d$ for the “asset in place” decreases in volatility $\sigma$ for the standard (put) option argument (Leland (1994)). The solid line shows that the default threshold $x^d$ for the “growth option” may either increase or decrease in volatility $\sigma$ in our setting, unlike Leland (1994). The (exogenously) given initial value $x_0$ for Leland (1994) is chosen to equal to the optimal investment threshold $x^i$ for the one growth option setting, when $\sigma = 20\%$. Parameter values are $\alpha = 35\%$, $r = 6\%$, $\tau = 20\%$, $\mu = 0$, $I = 1$, and $Q = 1$. 

44
Figure 3: Equity values $E_0(x)$ and the investment thresholds under all equity financing (with $\tau > 0$), (optimal) debt financing (with $\tau > 0$), and all equity financing (with $\tau = 0$). The respective investment thresholds are ordered sequentially: $x^{ae} > x^i > x^\ast$. The payoff at (different) exercising thresholds are equal under the three settings, in that $\Pi(x^{ae}) = V(x^i) = Qx^\ast/(r - \mu)$, as seen from the horizontal dashed line. Equity value $E_0(x)$ under all equity financing (with $\tau = 0$) is highest (labeled ‘AENT’); Equity value $E_0(x)$ under all equity financing (with $\tau > 0$) is the lowest (labeled ‘AE’); Equity value $E_0(x)$ under (optimal) debt financing (labeled ‘DF’), lies between the two equity values under equity financing (with $\tau = 0$ and with $\tau > 0$). The concave curve $V_1(x) - I$ is the payoff under debt financing from exercising, where $V_1(x)$ is the firm value after investing. Parameter values: $\alpha = 35\%$, $r = 6\%$, $\tau = 20\%$, $\mu = 0$, $\sigma = 20\%$, $I = 1$, and $Q = 1$. 
Figure 4: Comparative statics of various decision rules with respect to $c_1$ when the first debt is exogenously given, under APR. This figure plots the first default threshold $x_1^d$, the second investment threshold $x_2^i$, the ratio between the second investment and default thresholds $x_2^i/x_2^d$, the second coupon $c_2$, the credit spreads for the first and the second debt at $T_2$, and the total market leverage at $T_2$ as functions of the exogenously given coupon $c_1$. Parameter values: $\alpha = 35\%$, $r = 6\%$, $\tau = 20\%$, $\mu = 0$, $\sigma = 20\%$, $\omega = 0$, $I_2 = 1.5$, and $Q_2 = Q_1 = 1$. The credit spread for the first debt when originally issued is $c_1/F_1 - r = 0.77\%$. When increasing $c_1$, the face value $F_1$ also increases linearly, keeping the initial credit spread to be at $0.77\%$. 

Leverage at Investment Time

at 1\textsuperscript{st} investment time at T\textsubscript{1}\textsuperscript{i}
at 2\textsuperscript{nd} investment time at T\textsubscript{2}\textsuperscript{i}

Figure 5: Total market leverages at T\textsubscript{1}\textsuperscript{i} and T\textsubscript{2}\textsuperscript{i} as functions of the investment cost I\textsubscript{2} under full optimization, where investment thresholds (x\textsubscript{i}\textsubscript{1}, x\textsubscript{i}\textsubscript{2}) , default thresholds (x\textsubscript{d}\textsubscript{1}, x\textsubscript{d}\textsubscript{2}) , and coupon decisions (c\textsubscript{1}, c\textsubscript{2}) are all endogenously chosen. The solid and dashed lines in the left panel correspond to the total market leverage at T\textsubscript{1}\textsuperscript{i} and T\textsubscript{2}\textsuperscript{i}, respectively. This figure shows that the market leverage at T\textsubscript{1}\textsuperscript{i} is lower than the market leverage at T\textsubscript{2}\textsuperscript{i}. Moreover, the market leverage at T\textsubscript{1}\textsuperscript{i} is higher when the growth option is less attractive (higher I\textsubscript{2}) , consistent with our intuition on debt overhang. The solid line in the right panel gives the ratio of the total market leverage at T\textsubscript{1}\textsuperscript{i} (in the two growth option setting), scaled by the corresponding stand-alone one-growth option with I\textsubscript{1} and Q\textsubscript{1} (as in Section 4). The dashed line in the right panel gives the ratio of the total market leverage at T\textsubscript{2}\textsuperscript{i}, scaled by the corresponding stand-alone one-growth option with I\textsubscript{2} and Q\textsubscript{2} (as in Section 4). The horizontal dashed line (at unity) in the right panel indicates that there is no debt overhang in the second stage. Parameter values: \(\alpha = 35\%\), \(r = 6\%\), \(\tau = 20\%\), \(\mu = 0\), \(\sigma = 20\%\), \(\omega = 0\), \(I\textsubscript{1} = 1\), \(I\textsubscript{2} = 1.5\), \(Q\textsubscript{2} = Q\textsubscript{1} = 1\).
Figure 6: Comparative statics of various decision rules with respect to $c_1$ when the first debt is exogenously given: Comparisons between APR and pari passu. Unlike Figure 4, the horizontal axis is $c_1/c_1^*$, where $c_1^*$ is the optimal coupon level from the full optimization framework under APR (See Section 5.4). Scaling $c_1$ by $c_1^*$ gives us a notion about how much the potential debt overhang/risk shifting distortions are. The dashed lines depict the results under pari passu. We see significant differences between APR and pari passu. Parameter values: $\alpha = 35\%$, $r = 6\%$, $48\% = 20\%$, $\mu = 0$, $\sigma = 20\%$, $\omega = 0$, $I_2 = 1.5$, and $Q_2 = Q_1 = 1$. The credit spread for the first debt when originally issued is $c_1/F_1 - r = 0.77\%$. 

\[ $c_1/F_1$ \]
Table 1: The effects of debt seniority structure on equity value $E_1(x)$ with exogenously given debt. This table reports $E_{1}^{apr}(x_0)/E_{1}^{pp}(x_0) − 1$, the equity value ratio (minus unity) under APR and under pari passu. We choose $c_1 = 2c_1^*$, where $c_1^*$ is the optimal coupon under APR, and $x_0 = \left(\min\{x_{i,apr}^k, x_{i,pp}^k\} + \max\{x_{i,apr}^k, x_{i,pp}^k\}\right)/2$. The choice of this initial value $x_0$ ensures that the firm has not exercised the first default option nor the second growth option, under APR and pari passu. We show that $E_{1}^{apr}(x_0)/E_{1}^{pp}(x_0) − 1$ is significantly different from zero for various levels of $\mu$, $\sigma$, $\alpha$, and $\tau$. This table shows that debt seniority structure matters in terms of equity value when the firm does not have its initial investment and leverage decisions to mitigate anticipated debt overhang. Benchmark parameter values: $\alpha = 35\%$, $r = 6\%$, $\tau = 20\%$, $\mu = 0$, $\sigma = 20\%$, $\omega = 0$, $I_1 = 1$, $I_2 = 1.5$, and $Q_2 = Q_1 = 1$. For example, for the first comparative statics with respect to $\mu$, we are using all the benchmark parameter values other than $\mu = 0$.

Table 2: The effects of debt seniority structure on equity value $E_0(x)$ with endogenously chosen debt. This table reports $E_{0,apr}^{apr}(x) / E_{0,pp}^{pp}(x) - 1$, the equity value ratio (minus unity) under APR and under pari passu. The initial value is chosen such that the firm is willing to wait under both APR and pari passu, in that $x \leq \min\{x_{1,apr}^i, x_{1,pp}^i\}$. This table shows that $E_{0,apr}^{apr}(x) / E_{0,pp}^{pp}(x) - 1$ is less than 2% for essentially all levels of $\mu$, $\sigma$, $\alpha$, and $\tau$. This table shows that debt seniority structure matters little in terms of $E_0(x)$ when the firm may adjust its initial investment and leverage decisions to mitigate anticipated debt overhang. Benchmark parameter values: $\alpha = 35\%$, $r = 6\%$, $\tau = 20\%$, $\mu = 0$, $\sigma = 20\%$, $\omega = 0$, $I_1 = 1$, $I_2 = 1.5$, and $Q_2 = Q_1 = 1$. For example, for the first comparative statics with respect to $\mu$, we are using all the benchmark parameter values other than $\mu = 0$.
