Fiscal Rules and Discretion under Persistent Shocks

Marina Halac† Pierre Yared‡

September 21, 2013

Abstract

This paper studies the optimal level of discretion in policymaking. We consider a fiscal policy model where the government has time-inconsistent preferences with a present bias towards public spending. The government chooses a fiscal rule to trade off its desire to commit to not overspend against its desire to have flexibility to react to privately observed shocks to the value of spending. We analyze the optimal fiscal rule when the shocks are persistent. Unlike under i.i.d. shocks, we show that the ex-ante optimal rule is not sequentially optimal, as it provides dynamic incentives. The ex-ante optimal rule exhibits history dependence, with high shocks leading to an erosion of future fiscal discipline compared to low shocks, which lead to the reinstatement of discipline. The implied policy distortions oscillate over time given a sequence of high shocks, and can force the government to accumulate maximal debt and become immiserated in the long run.

1 Introduction

Governments often impose rules on themselves to constrain their behavior in the future. One of the most prevalent form of such rules are fiscal rules, typically adopted in response to rising public debts. In 2009, 80 countries had fiscal rules in place, a dramatic increase from 1990 when only seven countries had them.\footnote{See International Monetary Fund (2009). Of those 80 countries, 60 had a deficit limit, 60 a debt limit, and 25 a spending limit. These limits vary in their specification and the extent to which they adjust to levels of GDP and to the business cycle. Moreover, these limits also vary in the degree to which they are enforced. Some countries have formal escape clauses that allow for a temporary abandonment of fiscal rules; other countries—e.g., France and Germany in 2003—have instead abandoned rules less formally.}

Despite their prevalence, little is known about the optimal structure of fiscal rules. How much discipline does an optimal fiscal rule impose? How does this level of discipline evolve over time? And does an optimal rule restrict the growth of debt in the long run? Any theory of fiscal rules must take into account a fundamental tradeoff between commitment and flexibility: on the one hand, rules provide valuable commitment as they can limit distorted incentives in policymaking which result in a spending bias and excessive deficits; on the other hand, there is a cost of reduced flexibility as fiscal constitutions cannot spell out policy prescriptions for every single shock or contingency, and some discretion may be optimal.

This paper studies the tradeoff between commitment and flexibility in a dynamic self-control setting. In our model, a present-biased government privately observes a shock to the economy in each period, and a fiscal rule is a mechanism that assigns a policy as a function of the government’s reported shocks. We follow a similar approach to that used in Amador, Werning, and Angeletos (2006), but we depart from their work by considering an environment in which shocks are persistent over time.\footnote{See also Amador and Bagwell (2013), Ambrus and Egorov (2012), and Athey, Atkeson, and Kehoe (2005). All these papers consider settings with i.i.d. shocks.} We are motivated by the fact that shocks underlying fiscal policy are likely to be autocorrelated, consistent with the observation that fiscal policy variables are persistent in the data.\footnote{For example, see Barro (1990) for evidence.} As is well known, persistence introduces new difficulties into the mechanism design problem; we consider a simple framework that allows for a full characterization of the optimal mechanism.\footnote{Persistence complicates the mechanism design problem because single-crossing conditions generally used in the analysis may fail and a recursive representation is more difficult. Recent work addresses this issue in principal-agent and optimal taxation settings (see, e.g., Battaglini and Lamba, 2012, Farhi and Werning, 2010, Golosov, Troshkin, and Tsyvinski, 2011, and Pavan, Segal, and Toikka, 2010), but this analysis does not apply to our self-control setting where cross-subsidization across types is not possible.}

Our environment is a small open economy in which the government makes repeated spending and borrowing decisions. In each period, a shock to the social value of deficit-financed government spending—either low or high—is realized, where this shock follows a first-order...
The government in each period is benevolent ex ante, prior to the realization of the shock, but present-biased ex post, when it is time to choose fiscal policy. This preference structure results naturally from the aggregation of heterogeneous, time-consistent citizens’ preferences; see Jackson and Yariv (2012a,b). We assume that the shocks to the value of spending are privately observed by the government, capturing the fact that not all contingencies in fiscal policy are contractible or observable. A fiscal rule is defined as a mechanism in which the government reports the shock in each period and is assigned a policy for every reported shock. Note that in the absence of private information, the first-best policy could be implemented with full commitment; i.e. by giving the government no discretion and committing it to the efficient path of spending. Similarly, absent a present bias, the first best could be implemented with full flexibility; i.e. by giving the government full discretion to choose spending in each period. In the presence of both private information and a present bias, however, a tradeoff between commitment and flexibility arises, and the optimal rule is then not trivial.

We study the ex-ante optimal fiscal rule and the sequentially optimal fiscal rule. The ex-ante optimal rule is the optimal dynamic mechanism that the government chooses at the beginning of time. This is a sequence of spending and borrowing levels as a function of the history of the government’s reports, which maximizes ex-ante social welfare subject to a sequence of dynamic incentive compatibility constraints. The sequentially optimal rule, on the other hand, corresponds to a static mechanism that is chosen by the government in every period \( t \) (prior to the realization of the shock), which maximizes social welfare from \( t \) onward taking into account that future governments do the same.

Our motivation for studying sequentially optimal rules is twofold. First, in practice, fiscal rules often have a bite in the short term for the current fiscal year, but can be renegotiated and changed by the government in advance for the following year. Second, a central result from the previous literature is that the ex-ante optimal and sequentially optimal rules coincide when the shocks are i.i.d. That is, under the ex-ante optimal mechanism, at any given date (prior to the realization of the shock) the government would not want to change the continuation mechanism. The reason is that no dynamic incentives are provided, and the mechanism at any date depends only on the payoff-relevant states. Notably, this contrasts with the results of the principal-agent literature, where, even under i.i.d. shocks, dynamic incentives are provided to an agent with private information along the equilibrium path. The difference is due to

---

5We extend our analysis to a continuum of shocks in Appendix B.

6In addition, in a fiscal policy framework, there are various micro-foundations for how a deficit bias may emerge, including those in Aguiar and Amador (2011), Alesina and Perotti (1994), Alesina and Tabellini (1990), Battaglini and Coate (2008), Caballero and Yared (2010), Lizzeri (1999), Persson and Svensson (1989), and Tornell and Lane (1999). Our formulation of the government’s preferences corresponds to the quasi-hyperbolic consumption model; see Laibson (1997).

the fact that there is a single player in a self-control setting, and dynamic incentives cannot be provided by increasing one player’s welfare at the expense of another. Thus, under i.i.d. shocks, dynamic incentives would affect the government’s welfare on the equilibrium path (when reporting the shock truthfully) and off the equilibrium path (when misreporting the shock) equally, and therefore result in no welfare gains.

We first show that, as in the case of i.i.d. shocks, the sequentially optimal fiscal rule under persistent shocks is history independent and simple, as by definition dynamic incentives are not provided to the government. This rule can be implemented with a debt limit that is a function of only the payoff-relevant states, namely the current level of debt and the previous period’s shock which forecasts the current shock.

Our main result, however, shows that unlike under i.i.d. shocks, the ex-ante optimal rule does not coincide with the sequentially optimal rule when shocks are persistent. The ex-ante optimal rule takes into account that the government in every period learns about its current and future spending needs, and now provides dynamic incentives for the government not to overspend and overborrow. Specifically, consider a government that is tempted to overspend today when its needs are low. Dynamic incentives can be provided by introducing excessively lax and ex-post suboptimal rules tomorrow if the government chooses high levels of spending today. The expected cost to the government of such lax rules tomorrow is greater if spending needs are actually low today, as spending needs are then more likely to be low tomorrow. Thus, lax rules tomorrow affect welfare on and off the equilibrium path differently, and the threat of no discipline in the future ironically imposes discipline today.

We characterize the ex-ante optimal rule and the dynamics that it induces in fiscal policy. We show that this rule is history dependent: the mechanism at a given date is a function of not only the payoff-relevant states, but also the entire history of shocks. History dependence follows from the fact that the mechanism provides dynamic incentives. Intuitively, because the shock at date \( t - 2 \) predicts the realization of the shock at \( t - 1 \) (since shocks follow a first-order Markov process), the shock at \( t - 2 \) affects the relative tightness of incentive compatibility constraints at \( t - 1 \), which in turn affect the policies that are chosen at \( t \) in providing dynamic incentives at \( t - 1 \). In particular, the shock at date \( t - 2 \) tells us how likely it is that the shock to the value of spending will be low at \( t - 1 \), and thus how beneficial it is to make rules excessively lax at \( t \) following high spending by the government at \( t - 1 \).

We explicitly characterize the dynamics implied by the ex-ante optimal fiscal rule in an infinite horizon economy using a recursive technique similar to that developed by Fernandes and Phelan (2000) for a principal-agent setting. We show that high shocks to the value of spending lead to an erosion of future fiscal discipline compared to low shocks, which lead to the reinstatement of fiscal discipline. This is related to the “no distortion at the top” in standard adverse selection problems, which in our setting results in a resetting of the
mechanism whenever a low shock is realized. For a sequence of consecutive high shocks, we further show that fiscal policy exhibits oscillatory dynamics, with large (small) distortions being followed by relatively smaller (larger) distortions. The logic stems from the self-control nature of our problem: a reduction in fiscal discipline at date $t$ to provide dynamic incentives at $t-1$ relaxes incentive constraints at $t$, and hence implies that a smaller reduction in fiscal discipline at date $t+1$ is sufficient to provide dynamic incentives at $t$. Finally, we study the implied long-run debt dynamics when the market and social discount rates coincide. We show that while the self-insurance motive leads to the infinite accumulation of assets in the first best and the sequentially optimal rule, periods of non-discipline used to provide dynamic incentives in the ex-ante optimal rule can force the government accumulate maximal debt and become immiserated in the long run.

The paper is related to several literatures. First, as mentioned, the paper fits into the mechanism design literature on the tradeoff between commitment and flexibility. Most papers here consider i.i.d. environments, whereas we analyze the optimal dynamic mechanism when shocks are persistent. One exception is Bond and Sigurdsson (2011), who examine when contracts can overcome commitment problems in a setting with negatively correlated shocks. They do not study infinite horizon dynamics, which is our focus. Second, our paper relates to the literature on the political economy of fiscal policy. Most closely related is Azzimonti, Battaglini, and Coate (2010), who consider the quantitative welfare implications of a balanced budget rule in an i.i.d. setting where the government is present-biased towards pork-barrel spending. Our main departure is that we study optimal fiscal rules in a private information economy, and we use mechanism design tools to derive the optimal rule without restricting its structure. Third, our work is related to various papers studying principal-agent contracts under persistent private information, although, because our application is a self-control environment, their methods do not directly apply here. Finally, more broadly, our paper contributes to the literature on hyperbolic discounting and the benefits of commitment devices.

Section 2 describes the model. Section 3 defines the ex-ante optimal and sequentially optimal fiscal rules. Section 4 illustrates the main insights from our model using a simple three-period example. Section 5 characterizes optimal fiscal rules in the infinite horizon economy and their implications for debt in the long run. Section 6 concludes and describes some additional

8In addition to the work previously cited, see Sleet (2004) as well as Bernheim, Ray, and Yeltekin (2013) which considers the self-enforcement of commitment contracts. More generally, the paper relates to the literature on delegation in principal-agent settings, including Alonso and Matouschek (2008), Ambrus and Egorov (2009), and Holmström (1977, 1984).

9In addition to the work cited in fn. 6, see Acemoglu, Golosov, and Tsyvinski (2008), Azzimonti (2011), Krusell and Rios-Rull (1999), Song, Storesletten, and Zilibotti (2012), and Yared (2010).

10In addition to the work cited in fn. 4, see Golosov and Tsyvinski (2006), Halac (2012), Kapicka (2013), Strulovici (2011), and Williams (2011).

applications of our model. Formal proofs and supplementary analyses can be found in the Appendix.

2 The Model

We consider a simple model of fiscal policy in which a government makes repeated spending and borrowing decisions. Our environment is the same as that analyzed in Amador, Werning, and Angeletos (2006), with the exception that we allow for persistent private information.\textsuperscript{12}

At the beginning of each period, \( t \in \{0, 1, \ldots \} \), the government observes a shock to the economy, which is the government’s private information or \textit{type}. The government’s type can be low or high, \( \theta_t \in \{\theta_L, \theta_H\} \equiv \Theta \), where \( \theta_H > \theta_L > 0 \).\textsuperscript{13} This type follows a first-order Markov process, with \( p(\theta_{t+1} | \theta_t) \) corresponding to the probability of type \( \theta_{t+1} \) at date \( t+1 \) conditional on type \( \theta_t \) at date \( t \). We consider \( p(\theta^L | \theta^L) = p(\theta^H | \theta^H) \in [0.5, 1) \), and we compare the case where types are i.i.d., i.e. \( p(\theta^i | \theta^i) = 0.5 \) for \( \theta^i \in \{\theta^L, \theta^H\} \), to the case where types are persistent over time, i.e. \( p(\theta^i | \theta^i) > 0.5 \) for \( \theta^i \in \{\theta^L, \theta^H\} \).\textsuperscript{14}

In each period \( t \), following the realization of \( \theta_t \), the government chooses public spending \( g_t \geq 0 \) and debt \( b_{t+1} \) subject to a budget constraint:

\[
g_t = \tau + b_{t+1} / (1 + r) - b_t,
\]

where \( \tau > 0 \) is the exogenous fixed tax revenue collected by the government in each period, \( b_t \) is the level of debt with which the government enters the period, and \( r \) is the exogenous interest rate.\textsuperscript{15} \( b_0 \) is exogenous and \( \lim_{t \to \infty} b_{t+1} / (1 + r)^t = 0 \), so that all debts must be repaid and all assets must be consumed. Note that this setting does not allow for cross-subsidization across types. Specifically, in contrast to other mechanism design models such as Atkeson and Lucas (1992) and Thomas and Worrall (1990), the net present value of public spending at any point cannot be different for the low type and the high type.\textsuperscript{16} We also note that constraint (1) can be rewritten as a weak inequality constraint to allow for money burning without affecting any of our results. Such a weak inequality constraint would take into account the possibility

\textsuperscript{12}Amador, Werning, and Angeletos (2006) consider a two-period setting, but as shown in Amador, Werning, and Angeletos (2003), under i.i.d. shocks the results apply directly to a multiple-period environment.

\textsuperscript{13}Appendix B extends our analysis to an economy with a continuum of types.

\textsuperscript{14}Our main results are robust to considering \( p(\theta^i | \theta^i) < 0.5 \), although the intuition is different. Given that fiscal policy variables are positively autocorrelated in the data, we focus our attention on \( p(\theta^i | \theta^i) \geq 0.5 \). Our results are also robust to considering \( p(\theta^L | \theta^L) \neq p(\theta^H | \theta^H) \); we focus on the symmetric case to simplify the exposition.

\textsuperscript{15}Our analysis also applies if instead of having an exogenous tax revenue, social welfare is an increasing function of the budget deficit.

\textsuperscript{16}Other models that build on these papers and also feature cross-subsidization are Farhi and Werning (2007) and Sleet and Yeltekin (2006, 2008).
of introducing fines; we ignore this possibility here to simplify the exposition.\footnote{In the proofs of our results in the Appendix, we allow (1) to be a weak inequality and show that this constraint must bind in equilibrium.} The government’s welfare at date $t$, prior to the realization of its type $\theta_t$, is

$$\sum_{k=0}^{\infty} \delta^k \mathbb{E} \left[ \theta_{t+k} U(g_{t+k}) | \theta_{t-1} \right],$$

(2)

where $\theta_t U(g_t)$ is the social utility from public spending at date $t$ and $\delta$ is the discount factor. The government’s welfare after the realization of its type $\theta_t$ at date $t$, when choosing spending $g_t$, is

$$\theta_t U(g_t) + \beta \sum_{k=1}^{\infty} \delta^k \mathbb{E} \left[ \theta_{t+k} U(g_{t+k}) | \theta_t \right],$$

(3)

where $\beta \in (0, 1)$.

There are two important features of this environment. First, the government’s objective (3) following the realization of its type does not coincide with its objective (2) prior to this realization. In particular, the government’s welfare after $\theta_t$ is realized overweighs the importance of current public spending compared to its welfare before $\theta_t$ is realized. As mentioned in the Introduction, this structure arises naturally when the government’s preferences aggregate citizens’ preferences, even if the latter are time consistent. \textit{Jackson and Yariv (2012a)} show that with any heterogeneity in preferences, every non-dictatorial aggregation method that respects unanimity must be time inconsistent; moreover, any such method that is time separable must lead to a present bias.\footnote{Specifically, any such time-separable aggregation method will be utilitarian, and by the results in \textit{Jackson and Yariv (2012b)}, it will thus be present-biased.} Our formulation can also be motivated by political turnover. For instance, preferences such as these may emerge in settings with political uncertainty where policymakers place a higher value on public spending when they hold power and can make spending decisions. A present bias given by $\beta \in (0, 1)$ for a current policymaker can be interpreted in this sense as the probability that the policymaker will be part of the government in the next and all future periods. In these settings with turnover, policymakers are then biased towards present public spending relative to future public spending and as a result incur excessively high debts; see for example \textit{Aguiar and Amador (2011)}.

The second feature of our environment is that the realization of $\theta_t$—which affects the marginal social utility of public spending—is privately observed by the government. One possible interpretation is that $\theta_t$ is not verifiable ex-post by a rule-making body; therefore, even if $\theta_t$ is observable, fiscal rules cannot explicitly depend on the value of $\theta_t$.\footnote{Because our focus is a fiscal constitution, we implicitly rule out other punishments that citizens can inflict on policymakers such as replacement. See \textit{Ales, Maziero, and Yared (2012)} for a related model with private government information that allows for this possibility.} An alternative
interpretation is that the exact cost of public goods is only observable to the policymaker, who may be inclined to overspend on these goods. A third possibility is that citizens have heterogeneous preferences or heterogeneous information regarding the optimal level of public spending, and the government sees an aggregate that the citizens do not see (see Sleet, 2004).

To facilitate an explicit characterization of optimal fiscal rules, we make the following assumption.\(^\text{20}\)

**Assumption 1.** \(U(g_t) = \log(g_t)\).

Assumption 1 implies that welfare is separable with respect to the level of debt. To see this, define

\[
\widetilde{\theta}^i = \sum_{k=1}^{\infty} \delta^k \mathbb{E} \left[ \theta_{t+k} | \theta_t = \theta^i \right],
\]

for \(i = \{L, H\}\), so that at any date \(t\), \(\widetilde{\theta}_t = \widetilde{\theta}^i\) if \(\theta_t = \theta^i\). Let the savings rate at \(t\) be \(s_t \in [0, 1]\), corresponding to the fraction of lifetime resources which is not spent at \(t\):

\[
g_t = (1 - s_t)(1 + r)\tau/r - b_t.
\]

Using this notation and Assumption 1, welfare in (2), at date \(t\) prior to the realization of the type \(\theta_t\), can be rewritten as

\[
\sum_{k=0}^{\infty} \delta^k \mathbb{E} \left[ \theta_{t+k} U(1 - s_{t+k}) + \widetilde{\theta}_{t+k} U(s_{t+k}) | \theta_{t-1} \right] + \chi(b_t),
\]

for a constant \(\chi(b_t)\) which depends on \(b_t\).\(^\text{21}\) Analogously, welfare in (3), at date \(t\) following the realization of \(\theta_t\), can be rewritten as

\[
\theta_t U(1 - s_t) + \beta \widetilde{\theta}_t U(s_t) + \beta \sum_{k=1}^{\infty} \delta^k \mathbb{E} \left[ \theta_{t+k} U(1 - s_{t+k}) + \widetilde{\theta}_{t+k} U(s_{t+k}) | \theta_t \right] + \varphi(b_t),
\]

for a constant \(\varphi(b_t)\) which depends on \(b_t\).\(^\text{22}\) Given the representation in (6) and (7), hereafter we consider the problem of a government which chooses a savings rate \(s_t\) in every period \(t\). In this environment, the first-best policy is defined by a stochastic sequence of savings rates that satisfy \(s_{t}^{fb} = s^{fb}(\theta^i)\) if \(\theta_t = \theta^i\) for \(\theta^i \in \{\theta^L, \theta^H\}\), where

\[
\theta^i U'(1 - s^{fb}(\theta^i)) = \widetilde{\theta}^i U'(s^{fb}(\theta^i)),
\]

\(^{20}\)This assumption is made in previous work studying economies with hyperbolic discounting, such as Barro (1999). Our main result that dynamic incentives are provided under persistent shocks while not under i.i.d. shocks does not depend on this assumption.

\(^{21}\)This constant is equal to \(\sum_{k=0}^{\infty} \delta^k \mathbb{E} \left[ \theta_{t+k} U((1 + r)^k[r(1 + r)/r - b_t]) | \theta_{t-1} \right] \).

\(^{22}\)This constant is equal to \(\theta_t U(r(1 + r)/r - b_t) + \beta \sum_{k=1}^{\infty} \delta^k \mathbb{E} \left[ \theta_{t+k} U((1 + r)^k[r(1 + r)/r - b_t]) | \theta_t \right] \).
3 Equilibrium Definition

We define a fiscal rule as a mechanism where the government reports the shock in every period and is assigned a policy as a function of the reports. We distinguish between the ex-ante optimal rule and the sequentially optimal rule. The ex-ante optimal rule is a dynamic mechanism chosen by the government at the beginning of time. In contrast, the sequentially optimal rule is a static mechanism chosen in every period by the current government, taking into account the future static mechanisms chosen by future governments.

We let \( \theta^t = (\theta_0, \theta_1, \ldots, \theta_t) \in \Theta^t \) denote the history of shocks through time \( t \).

3.1 Ex-ante Optimal Rule

Let \( h_{t-1} = (\hat{\theta}_0, \hat{\theta}_1, \ldots, \hat{\theta}_{t-1}) \in \Theta^{t-1} \) be the history of reported types through time \( t - 1 \). A mechanism is a sequence of savings rates \( s_t(h_{t-1}, \hat{\theta}_t) \) for all \( \{(h_{t-1}, \hat{\theta}_t)\}_{t=0}^{\infty} \), which effectively specify levels of public spending \( g_t(h_{t-1}, \hat{\theta}_t) \) and debt \( b_{t+1}(h_{t-1}, \hat{\theta}_t) \), as a function of the history of past reports and the current report.

Given the mechanism, the government chooses a reporting strategy \( m_t(h_{t-1}, \theta_t) \) for all \( \{(h_{t-1}, \theta_t)\}_{t=0}^{\infty} \), where \( \theta_t \) is the government’s type at date \( t \) and \( m_t(h_{t-1}, \theta_t) \in \{\theta^L, \theta^R\} \) is the government’s report of its type at \( t \). We restrict attention to public strategies, that is, strategies that depend only on the public history—reports and policies—and on the government’s current private information, but not on privately observed history. While common in the literature, this restriction is not without loss; see Section 4 for a discussion. It follows by standard arguments that if all future governments choose public strategies, and if the mechanism is a function of the public history, then the current government’s best response is also a public strategy. From the Revelation Principle, we can restrict attention to truth-telling equilibria in which \( m_t(h_{t-1}, \theta_t) = \theta_t \) for all \( h_{t-1} \) and \( \theta_t \).

A perfect Bayesian equilibrium of this revelation game is a mechanism and a reporting strategy such that the budget constraint (1) is satisfied in every period following every history, and the policy under the mechanism is incentive compatible, meaning that following every history and type realization, the government prefers to report \( m_t(h_{t-1}, \theta_t) = \theta_t \) rather than \( m_t(h_{t-1}, \theta_t) = \hat{\theta}_t \neq \theta_t \). An ex-ante optimal rule in this framework is one that selects a mechanism and a reporting strategy that maximize the ex-ante welfare (6) in period 0.

We formulate the ex-ante optimal rule as a solution to a sequence program. Given history \( \theta^{t-1} \), let \( W_{t+1}(\theta^{t-1}, \theta_t) \) be the expected continuation value from \( t+1 \) on, normalized by \( b_t(\theta^{t-1}) \), for a type \( \theta_t \) who truthfully reports \( \hat{\theta}_t = \theta_t \):

\[
W_{t+1}(\theta^{t-1}, \theta_t) = \sum_{\theta_{t+1} \in \{\theta^L, \theta^R\}} p(\theta_{t+1}|\theta_t) \left[ \delta W_{t+2}(\theta^{t-1}, \theta_t, \theta_{t+1}) + s_{t+1}(\theta^{t-1}, \theta_t, \theta_{t+1}) \right].
\]
In contrast, given history $\theta^{t-1}$, let $V_{t+1}(\theta^{t-1}, \hat{\theta}_t)$ be the expected continuation value from $t + 1$ on, normalized by $b_t(\theta^{t-1})$, for a type $\theta_t$ who lies and reports $\hat{\theta}_t \neq \theta_t$:

$$V_{t+1}(\theta^{t-1}, \hat{\theta}_t) = \sum_{\theta_{t+1} \in \{\theta^L, \theta^H\}} p(\theta_{t+1} | \theta_t) \left[ \theta_{t+1} U(1 - s_{t+1}(\theta^{t-1}, \hat{\theta}_t, \theta_{t+1})) + \tilde{\theta}_{t+1}(s_{t+1}(\theta^{t-1}, \hat{\theta}_t, \theta_{t+1})) + \delta W_{t+2}(\theta^{t-1}, \hat{\theta}_t, \theta_{t+1}) \right].$$ \hspace{1cm} (10)

Note that in the special case of i.i.d. shocks, expectations over future shocks do not depend on the current shock $\theta_t$, implying that $W_{t+1}(\theta^{t-1}, \hat{\theta}_t) = V_{t+1}(\theta^{t-1}, \hat{\theta}_t)$.

Using (7), the incentive compatibility constraint for a government of type $\theta_t$ is

$$\theta_t U(1 - s_t(\theta^{t-1}, \theta_t)) + \beta \tilde{\theta}_t U(s_t(\theta^{t-1}, \theta_t)) + \beta \delta W_{t+1}(\theta^{t-1}, \theta_t)$$

$$\geq \theta_t U(1 - s_t(\theta^{t-1}, \hat{\theta}_t)) + \beta \tilde{\theta}_t U(s_t(\theta^{t-1}, \hat{\theta}_t)) + \beta \delta V_{t+1}(\theta^{t-1}, \hat{\theta}_t) \text{ for } \hat{\theta}_t \neq \theta_t \text{ and all } \theta^{t-1}. \hspace{1cm} (11)$$

Condition (11) says that the government prefers to report its true type $\theta_t$ rather than to lie and report $\hat{\theta}_t \neq \theta_t$. To understand this constraint, note that the government’s true type $\theta_t$ not only directly affects the government’s immediate payoff by determining the marginal cost of current savings, but, if shocks are persistent, it can also affect the government’s continuation payoff by changing the expectations over the realizations of future types.

Let $\rho = \{\{s_t(\theta^t), W_{t+1}(\theta^t), V_{t+1}(\theta^t)\}_{\theta^t}^\infty\}_{t=0}^\infty$ be a stochastic sequence of savings rates and continuation values. The ex-ante optimal rule solves the following sequence problem:

$$\max_{\rho} \sum_{\theta_0 \in \{\theta^L, \theta^H\}} p(\theta_0 | \rho_{-1}) \left[ \theta_0 U(1 - s_0(\theta^0)) + \tilde{\theta}_0 U(s_0(\theta^0)) + \delta W_1(\theta^0) \right]$$ \hspace{1cm} (12)

s.t. (9), (10), and (11).

It is clear that the solution to this program is invariant to the initial level of debt $b_0$.

### 3.2 Sequentially Optimal Rule

The sequentially optimal fiscal rule is the one that results if, at every history, the government chooses a static mechanism that maximizes social welfare given that future governments will do the same. That is, given $\theta_t$ and $b_t$, the government chooses a mechanism $\{g_t(\hat{\theta}_t), b_{t+1}(\hat{\theta}_t)\}$, assigning a level of spending and debt conditional on the report $\hat{\theta}_t$, which maximizes social welfare taking the actions of future governments as given. The future government knows the true value of $\theta_t$ and, given $\theta_t$ and $b_{t+1}(\hat{\theta}_t)$, it analogously chooses an optimal static mechanism taking the actions of future governments as given.

---

23 Because there are only two types, we only need to define one such expected continuation value.

24 Because $\theta_t$ follows a first-order Markov process, the single period deviation principle holds.
The sequentially optimal rule thus solves the following problem:

\[
J(\theta_{t-1}, b_t) = \max_{\{g_t(\theta_t), b_{t+1}(\theta_t)\}} \sum_{\theta_t \in \{\theta_L, \theta_H\}} p(\theta_t|\theta_{t-1}) \left( \theta_t U(g_t(\theta_t)) + \delta J(\theta_t, b_{t+1}(\theta_t)) \right)
\]  
\[
\text{s.t.}
\]
\[
g_t(\theta_t) = \tau + b_{t+1}(\theta_t)/(1 + r) - b_t \quad \text{and}
\]
\[
\theta_t U(g_t(\theta_t)) + \beta \delta J(\theta_t, b_{t+1}(\theta_t)) \geq \theta_t U(g_t(\hat{\theta}_t)) + \beta \delta J(\theta_t, b_{t+1}(\hat{\theta}_t)) \quad \text{for } \hat{\theta}_t \neq \theta_t.
\]

\(J(\theta_{t-1}, b_t)\) is the value at \(t\) under the payoff-relevant states \(\theta_{t-1}\) and \(b_t\) if the current government chooses an optimal static mechanism given that future governments do the same. In a sense, \(J(\theta_{t-1}, b_t)\) thus corresponds to the solution of a two-period mechanism design problem. In choosing its report \(\hat{\theta}_t\), the government’s flow welfare is \(\theta_t U(g_t(\hat{\theta}_t))\) and its continuation welfare is \(J(\theta_t, b_{t+1}(\hat{\theta}_t))\). Condition (15) is the incentive compatibility constraint, where the government knows that if it lies and reports \(\hat{\theta}_t \neq \theta_t\), this affects its payoff from tomorrow onward only through the implied level of debt \(b_{t+1}(\hat{\theta}_t)\), since, given \(b_{t+1}(\hat{\theta}_t)\), the government which knows the true value of \(\theta_t\) will choose an optimal static mechanism going forward. We interpret the sequentially optimal fiscal rule that emerges from this recursion as a rule that has a bite in the short term, but can be renegotiated for the future.25

In the recursive program defined above, \(J(\cdot)\) may have multiple solutions. We select a unique solution by considering the limit of a finite horizon economy with end date \(T\) as \(T\) approaches infinity. \(J(\theta_{t-1}, b_t)\) is thus characterized recursively via backward induction. In Appendix A, we show that under log utility the solution to (13)–(15) admits a savings rate \(s_t(\theta_t)\) for each \(\theta_t\) that is invariant to the level of debt \(b_t\) and only depends on the previous shock \(\theta_{t-1}\), and, hence, using the welfare representation in (6) and (7) and given \(\theta_{t-1}\), (13)–(15) can be rewritten as:

\[
\max_{\{s_t(\theta_t)\} \theta_t \in \{\theta_L, \theta_H\}} \sum_{\theta_t \in \{\theta_L, \theta_H\}} p(\theta_t|\theta_{t-1}) \left( \theta_t U(1 - s_t(\theta_t)) + \tilde{\theta}_t U(s_t(\theta_t)) \right)
\]  
\[
\text{s.t.}
\]
\[
\theta_t U(1 - s_t(\theta_t)) + \beta \tilde{\theta}_t U(s_t(\theta_t)) \geq \theta_t U(1 - s_t(\tilde{\theta}_t)) + \beta \tilde{\theta}_t U(s_t(\tilde{\theta}_t)) \quad \text{for } \tilde{\theta}_t \neq \theta_t.
\]

Clearly, the sequentially optimal rule must satisfy the constraints of the problem defined by the ex-ante optimal rule in (12). To see this, note that the incentive compatibility constraint (17) is more strict than the constraint (11), as by definition the solution to (16)–(17) must admit a sequence of savings rates satisfying \(W_{t+1}(\theta_{t-1}, \theta_t) \geq V_{t+1}(\theta_{t-1}, \theta_t)\). Thus, naturally,

25In our context in which we assume commitment to a rule within the period, this notion of sequential optimality is related to the notion of reconsideration-proofness in Kocherlakota (1996) and renegotiation-proofness in Farrell and Maskin (1989) and Strulovici (2011).
the sequentially optimal rule provides weakly lower welfare than the ex-ante optimal rule.

4 Three-Period Example

To provide intuition for our main results, we start by considering a three-period economy with \( t \in \{0, 1, 2\} \). The purpose is threefold. First, we show that in contrast with the case of i.i.d. shocks, when shocks are persistent, the ex-ante optimal rule does not coincide with the sequentially optimal rule. We discuss how the difference between the two rules depends on parameters such as the level of persistence and the degree of time inconsistency. Second, we show that, also unlike under i.i.d shocks, the ex-ante optimal rule under persistent shocks exhibits history dependence, that is, the mechanism at \( t = 1 \) depends on more than the payoff-relevant variables at \( t = 1 \). Finally, we describe properties of the solution that provide some insight into the dynamics of the infinite horizon economy discussed in Section 5.

Given log utility and the arguments of Section 3, one can think of the government as choosing a savings rate \( s_0 (\theta_{-1}, \theta_0) \) at date 0 and a savings rate \( s_1 (\theta_{-1}, \theta_0, \theta_1) \) at date 1.\(^{26}\) It is immediate to show that these savings rates under the first-best policy are higher than the savings rates the government would choose were it allowed to flexibly choose borrowing and spending in each period.\(^{27}\) Under full flexibility, the government would be left with excessively high debt in period 2—it is in this sense that fiscal rules can be beneficial by inducing more government saving.

We begin by studying the sequentially optimal rule, which can be solved for by backward induction. At date 1, the government solves program (16)–(17), where \( \tilde{\theta}_1 \) is given by \( \delta \mathbb{E}[\theta_2 | \theta_1] \). To simplify the analysis, we assume that \( \theta^L \) and \( \theta^H \) are relatively close to each other:

\[
\frac{\theta^H}{\theta^L} < \frac{1}{\beta}.
\] (18)

Condition (18) implies that the first-best savings rate at date 1, defined by (8), is not incentive compatible for the low type, who would want to pretend to be a high type so as to spend and borrow more. Moreover, this condition implies that the optimal static mechanism at date 1 features pooling; following the realization of \( \theta_0 \), the sequentially optimal rule assigns a fixed savings rate, independent of the type at date 1.\(^{28}\) This pooled savings rate is chosen optimally

\(^{26}\)Note that savings at date 2 are always equal to zero, since this is the final period.

\(^{27}\)In the first-best solution, the savings rates in periods 0 and 1 are \( \delta \mathbb{E}[\theta_1 + \delta \theta_2 | \theta_0] / (\theta_0 + \delta \mathbb{E}[\theta_1 + \delta \theta_2 | \theta_0]) \) and \( \mathbb{E}[\theta_2 | \theta_1] / (\theta_1 + \delta \mathbb{E}[\theta_2 | \theta_1]) \) respectively. In contrast, under full flexibility, these rates are \( \beta \delta \mathbb{E}[\theta_1 + \delta \theta_2 | \theta_0] / (\theta_0 + \beta \delta \mathbb{E}[\theta_1 + \delta \theta_2 | \theta_0]) \) and \( \beta \mathbb{E}[\theta_2 | \theta_1] / (\theta_1 + \beta \delta \mathbb{E}[\theta_2 | \theta_1]) \) respectively.

\(^{28}\)Intuitively, separation when types are sufficiently close is suboptimal because it would require excessively low savings by the high type so as to satisfy the incentive compatibility constraint of the low type. A formal proof that pooling is optimal in this case follows closely the steps of the proof of Proposition 1 in Appendix C.
given the probabilities of a high and low type at date 1, so it is given by

\[
\mathbb{E}[\theta_1|\theta_0 = \theta^i]U'(1 - s_1(\theta_{-1}, \theta^i)) - \delta \mathbb{E}[\theta_2|\theta_0 = \theta^i]U'(s_1(\theta_{-1}, \theta^i)) = 0 \quad (19)
\]

for \( \theta^i \in \{\theta^L, \theta^H\} \), where, with some abuse of notation, we have written \( s_1(\cdot) \) as a function of \( \theta_{-1} \) and \( \theta_0 \) only given that savings at date 1 do not depend on \( \theta_1 \) under pooling.

Consider next the ex-ante optimal rule. Suppose by contradiction that the ex-ante optimum and the sequential optimum coincide at date 1. We show that it is then possible to perturb the ex-ante optimal mechanism in a way that reduces welfare from the perspective of date 1 but increases welfare from the perspective of date 0, thus increasing ex-ante welfare and contradicting the assumption that the two rules coincide at date 1.

Assume that at date 0 the incentive compatibility constraint binds for the low type and is slack for the high type. This means that the low type is under-saving relative to first best, and he cannot be induced to save more as he would then want to pretend to be a high type to save less. Formally, the low type is indifferent between reporting the truth and receiving a payoff equal to

\[
\theta^L U(1 - s_0(\theta_{-1}, \theta^L)) + \beta \delta \mathbb{E}[\theta_1 + \delta \theta_2|\theta_0 = \theta^L] U(s_0(\theta_{-1}, \theta^L)) \\
+ \beta \delta (\mathbb{E}[\theta_1|\theta_0 = \theta^L] U(1 - s_1(\theta_{-1}, \theta^L)) + \delta \mathbb{E}[\theta_2|\theta_0 = \theta^L] U(s_1(\theta_{-1}, \theta^L))
\]

and lying and receiving a payoff equal to

\[
\theta^L U(1 - s_0(\theta_{-1}, \theta^H)) + \beta \delta \mathbb{E}[\theta_1 + \delta \theta_2|\theta_0 = \theta^L] U(s_0(\theta_{-1}, \theta^H)) \\
+ \beta \delta (\mathbb{E}[\theta_1|\theta_0 = \theta^L] U(1 - s_1(\theta_{-1}, \theta^H)) + \delta \mathbb{E}[\theta_2|\theta_0 = \theta^L] U(s_1(\theta_{-1}, \theta^H))
\]

where, by the contradiction assumption that the mechanism is sequentially optimal at date 1, \( s_1(\theta_{-1}, \theta^i) \) is the pooled savings rate given by (19). Clearly, the low type could be induced to save more at date 0 if his payoff from pretending to be a high type could be reduced. Note that this payoff can be reduced by changing either the savings rate that is assigned at date 0 given a high reported type at date 0, or the savings rate that is assigned at date 1 given a high reported type at date 0. Moreover, the effect on welfare of changing the savings rate at date 1 depends on the probabilities of a low type and a high type at date 1, which under persistent shocks depend on the realized type at date 0.

With this observation in mind, consider a perturbation that reduces the savings rate at date 1 given a high type at date 0, \( s_1(\theta_{-1}, \theta^H) \), by \( \epsilon > 0 \) arbitrarily small. This perturbation clearly reduces equilibrium welfare from date 1 onward, that is, welfare at date 1 given a truthful report of \( \hat{\theta}_0 = \theta^H \) at date 0, as it induces overspending at date 1. However, from
the envelope condition in (19), this is a second-order loss, so this effect approaches 0 as \( \varepsilon \) approaches 0. In contrast, consider the effect of the perturbation on off-equilibrium welfare from date 1 onward, that is, welfare at date 1 given a non-truthful report of \( \hat{\theta}_0 = \theta^H \) at date 0. As \( \varepsilon \) approaches 0, this effect takes the same sign as

\[
\mathbb{E}[\theta_1|\theta_0 = \theta^L]U'(1 - s_1(\theta_{-1}, \theta^H)) - \delta \mathbb{E}[\theta_2|\theta_0 = \theta^L]U'(s_1(\theta_{-1}, \theta^H)).
\]  

(20)

If shocks are i.i.d., \( \mathbb{E}[\theta_1|\theta_0 = \theta^L]/\mathbb{E}[\theta_2|\theta_0 = \theta^L] = \mathbb{E}[\theta_1|\theta_0 = \theta^H]/\mathbb{E}[\theta_2|\theta_0 = \theta^H] \), so, given (19), (20) must equal zero. This means that the perturbation affects continuation welfare on and off the equilibrium path equally and hence cannot improve ex-ante welfare. In contrast, when shocks are persistent, \( \mathbb{E}[\theta_1|\theta_0 = \theta^L]/\mathbb{E}[\theta_2|\theta_0 = \theta^L] < \mathbb{E}[\theta_1|\theta_0 = \theta^H]/\mathbb{E}[\theta_2|\theta_0 = \theta^H] \), so (20) must be negative. Given (19), this means that the perturbation reduces continuation welfare off the equilibrium path without affecting continuation welfare on path. Therefore, the low type’s incentive compatibility constraint at date 0 can be relaxed at no social cost, and ex-ante welfare can be increased.

The intuition behind the perturbation is simple. In every period, the government learns about its current spending needs. If shocks are persistent, the current shock also informs the government about its future spending needs. The government has a temptation to overspend today even if its needs are low, but it maximizes social welfare from tomorrow on. The ex-ante optimal rule then has the feature that it becomes excessively lax in the future if spending is high today. The reason is that the expected cost of lax rules tomorrow is greater if spending needs are low today, as spending needs are then likely to be low tomorrow. As a result, the threat of no discipline in the future ironically imposes discipline today.

We illustrate the properties of the ex-ante optimum and the sequential optimum with a numerical example.\(^{29}\) It can be shown that under (18), the ex-ante optimal rule also features pooling at date 1; thus, under the two rules, the savings rate at date 1 is independent of the realized type at date 1. Figure 1 shows this savings rate, \( s_1(\theta_{-1}, \theta^i) \), in the ex-ante optimal (“eo”) and sequentially optimal (“so”) rules for \( \theta_0 = \theta^L \) (“\( s^L_1 \)” and \( \theta_0 = \theta^H \) (“\( s^H_1 \)”), given \( \theta_{-1} = \theta^H \), as a function of the persistence of types, denoted \( \alpha \equiv p(\theta^i|\theta^i) \) in the figure.

Three points are evident in Figure 1. First, consistent with the perturbation just described, the figure shows that the ex-ante optimal savings rate at date 1 following \( \theta_0 = \theta^H \) is below the sequentially optimal rate. As explained, inducing overspending ex post is efficient ex ante because it allows to relax the low type’s incentive compatibility constraint and curb his spending at date 0. Second, the figure shows that following \( \theta_0 = \theta^L \), the ex-ante optimal savings rate at date 1 coincides with the sequentially optimal rate. The logic for this “no distortion at the top” also stems from the low type’s incentive compatibility constraint at

\(^{29}\)We consider \( \delta = 0.9 \), \( \beta = 0.6 \), \( \theta^L = 2 \), and \( \theta^H = 3 \).
Figure 1: Savings rate at $t = 1$ in the ex-ante and sequentially optimal rules given $\theta_{-1} = \theta^H$.

date 0: to relax this constraint, the ex-ante optimal rule maximizes the continuation welfare for the low type given a truthful report at date 0, which corresponds to assigning the optimal static rate at date 1. Finally, the figure shows how the savings rate at date 1 depends on the persistence of types, and in particular that the ex-ante optimal and sequentially optimal rates coincide if types are i.i.d. ($\alpha = 0.5$) or fully persistent ($\alpha = 1$). Intuitively, in these cases, $\mathbb{E}[\theta_1|\theta_0 = \theta^i] = \mathbb{E}[\theta_2|\theta_0 = \theta^i]$, so the marginal benefit of spending at dates 1 and 2 is the same. Given (19), this means that the sequentially optimal rate at date 1 is independent of $\theta_0$, and thus any perturbation would affect welfare on and off the equilibrium path equally.

To gain further intuition for the ex-ante optimal rule, the left graph in Figure 2 explores how the savings rate at date 1 following $\theta_0 = \theta^H$ depends on the time inconsistency problem. The graph shows that the difference between the sequentially optimal and ex-ante optimal rates is smaller the larger is the government’s present bias, i.e. the lower is $\beta$. The logic is simple: the less the government at date 0 cares about its welfare at date 1, the less effective is a distortion in the sequentially optimal rate at date 1 to relax incentive compatibility constraints at date 0. Since the welfare cost of the distortion at date 1 is independent of the degree of present bias, it follows that the distortion must be smaller when this bias is larger.

Finally, the right graph in Figure 2 explores whether the ex-ante optimal mechanism exhibits history dependence. The graph shows that, indeed, the ex-ante optimal savings rate

---

We take $\beta' = 0.4$ and $\beta'' = 0.6$. Note that given other parameters fixed, $\beta$ must be low enough for condition (18) to be satisfied. In our numerical example, (18) requires $\beta \leq 2/3$. Note also that the sequentially optimal savings rate is independent of $\beta$. 

at date 1 following $\theta_0 = \theta^H$ depends on the history, namely on $\theta_{-1}$.\footnote{The savings rate at date 1 following $\theta_0 = \theta^L$ is history independent, as it is sequentially optimal.} Specifically, this rate is lower and further away from the sequentially optimal rate if $\theta_{-1} = \theta^L$ than if $\theta_{-1} = \theta^H$, so fiscal rules become more excessively lax after a high shock at date 0 if $\theta_{-1} = \theta^L$. The intuition is that $\theta_{-1}$ affects the distribution of types at date 0, and thus the benefits and costs of perturbing the savings rate at date 1. Recall that the benefit of the perturbation is that it relaxes the low type’s incentive compatibility constraint at date 0 and allows to increase savings given $\theta_0 = \theta^L$; the cost on the other hand is that it induces an ex-post suboptimal savings rate at date 1 given $\theta_0 = \theta^H$. If $\theta_{-1} = \theta^L$, the probability of $\theta_0 = \theta^L$ is higher, and therefore the relative benefits of the perturbation are larger.

Before turning to the infinite horizon economy, we use our three-period example to briefly discuss our restriction to public strategies. As previously noted, this restriction is not without loss. Suppose that the government’s strategy can depend on its private history as follows: in addition to reporting its type at date 1, the date-1 government also reports the type that was realized at date 0. We show that this extension of the message space allows to increase efficiency by relaxing the incentive compatibility constraints at date 0.

Specifically, consider a mechanism that is identical to the ex-ante optimal mechanism (in public strategies), so it does not depend on the government’s report at date 1 of its type at date 0, except in one circumstance: when the date-0 government reported that its type was high and the date-1 government reports that its type was low at date 0 and is high at date 1. In
this case, the mechanism assigns the date-1 government a savings rate such that the high type at date 1 is indifferent between this rate and the rate it would be assigned under the ex-ante optimal mechanism. By construction, since the high type at date 1 wants to spend more than what is allowed in the ex-ante optimum, the new savings rate is lower. Moreover, it can be verified that this rate satisfies incentive compatibility constraints; in particular, the low type at date 1 prefers its assigned savings rate at date 1 in the ex-ante optimum to the new rate. Finally, because the date-1 government can now effectively “rat out” the date-0 government and cause savings to be even lower at date 1, it is clear that this modification makes it less attractive for the low type at date 0 to deviate and report to be a high type. Therefore, private strategies can in this way relax incentive compatibility constraints and enhance efficiency.32 While mechanisms using private strategies are interesting, in this paper we focus on public strategies as a first step to understanding optimal fiscal rules when shocks are persistent.

5 Optimal Fiscal Rules

This section characterizes the optimal fiscal rules in an infinite horizon economy. Because the sequentially optimal rule is simple, we first study this rule in Subsection 5.1 and then use it as a benchmark in describing the ex-ante optimal rule in Subsection 5.2. In Subsection 5.3, we consider the implications of these rules for the level of debt in the long run.

We develop our characterization under the assumption that types are relatively close to each other.33

Assumption 2.

$$\frac{\theta_H}{\theta_L} - \frac{\tilde{\theta}_H}{\tilde{\theta}_L} < \frac{1 - p(\theta^i|\theta^j)}{p(\theta^i|\theta^j)} \left( \frac{1}{\beta} - 1 \right).$$

Assumption 2 is implied by condition (18) in the three-period example of Section 4 if the level of persistence is low enough, i.e. if $p(\theta^i|\theta^j) \geq 1/2$ is sufficiently close to 1/2.34 We discuss the intuition and implications of Assumption 2 in the following subsections.

5.1 Sequentially Optimal Rule

Consider program (16)–(17) defining the sequentially optimal fiscal rule. Given Assumption 2, it can be shown that this rule features pooling: the savings rate $s_t(\theta^i)$ is independent of the

---

32The proposed modification allows to increase efficiency under private strategies when shocks are discrete. On the other hand, Amador, Werning, and Angeletos (2003) show that with a continuum of i.i.d. shocks, there is no loss in focusing on public strategies because there is zero mass on all types.

33This assumption is consistent with the extension to a continuum of types in Appendix B.

34The strict inequality in Assumption 2 cannot be satisfied under full persistence ($p(\theta^i|\theta^j) = 1$). However, our problem in that case is rather trivial as the first-best savings rate is the same for both types. If types are close enough, the assumption is satisfied for any persistence level, including those arbitrarily close to 1.
realization of $\theta_t$ and depends only on $\theta_{t-1}$, which is used in predicting the value of $\theta_t$. This is stated formally in the proposition below.

**Proposition 1 (sequential optimum).** For all $\theta^t$ and $\theta^k$, the sequential optimum features

$$s_t(\theta^t) = s_k(\theta^k) \text{ if } \theta_{t-1} = \theta_{k-1}.$$ 

Moreover, $s_t(\theta^t)$ satisfies

$$\mathbb{E}[\theta_t|\theta_{t-1}]U'(1 - s_t(\theta^t)) - \mathbb{E}[\tilde{\theta}_t|\theta_{t-1}]U'(s_t(\theta^t)) = 0. \quad (21)$$

**Proof.** See Appendix C.

The intuition for this result is analogous to that in the three-period example of Section 4, where the optimal static mechanism features pooling when types are sufficiently close. Here the result follows from Assumption 2, which implies that the analog of condition (18) used for the three-period economy holds in the infinite horizon economy.\(^{35}\)

Given the budget constraint (1), Proposition 1 says that the sequentially optimal rule at date $t$ prescribes a level of debt $b_{t+1}(\theta^t)$ as a function of $\theta_{t-1}$ and $b_t(\theta^{t-1})$ only. If $\theta_{t-1} = \theta^H$, the prescribed level of debt is higher than if $\theta_{t-1} = \theta^L$, as a high shock is then more likely and thus the sequentially optimal level of deficit-financed spending at date $t$ is higher. Furthermore, if $b_t(\theta^{t-1})$ is relatively high, then $b_{t+1}(\theta^t)$ must also be relatively high to facilitate the servicing of the debt while simultaneously providing public goods. A useful implication is that the sequential optimum can be implemented with a renegotiated debt limit.

**Corollary 1.** The sequentially optimal rule at any date $t$ can be implemented with a history-independent debt limit, $\bar{b}(\theta_{t-1}, b_t(\theta^{t-1}))$.

It follows from Assumption 2 and equation (21) that under the sequentially optimal rule, both the low type and the high type would like to borrow and spend more than they are allowed to. Thus, the sequentially optimal rule takes the form of a renegotiated debt limit where, given $\theta_{t-1}$ and $b_t(\theta^{t-1})$, both types choose the maximum allowable debt.\(^{36}\)

### 5.2 Ex-ante Optimal Rule

We now consider the ex-ante optimal fiscal rule defined in (12). We first develop a recursive representation of the problem and then characterize the solution.

\(^{35} \)Specifically, this condition is $\frac{\theta^H/\theta^H}{\theta^L/\theta^L} < \frac{1}{\beta}$.\(^{36} \)In Appendix B, we show that these results extend to an economy with a continuum of types, although in that case some types choose to borrow below the debt limit.
5.2.1 Recursive Representation

Our recursive representation is similar in spirit to that of Fernandes and Phelan (2000), who develop a recursive technique to study a principal-agent problem under persistent shocks. The idea of this representation is to solve program (12) by choosing \( s_t(\theta^t) \) and \( V_{t+1}(\theta^t) \) defined in (10) sequentially for each history \( \theta^{t-1} \), where associated with each choice of \( V_{t+1}(\theta^t) \) is some continuation welfare \( W_{t+1}(\theta^t) \) that is a function of the realized type \( \theta_t \) and the chosen \( V_{t+1}(\theta^t) \). To characterize this value of \( W_{t+1}(\theta^t) \), let \( W(\theta^t, V^t) \) for \( \theta^t \in \{\theta^L, \theta^H\} \) correspond to the solution to (12) given \( \theta_{-1} = \theta^t \) and subject to the following additional constraint:

\[
V = \sum_{\theta_0 \in \{\theta^L, \theta^H\}} p(\theta_0 | \theta_{-1} = \theta^{-1}) [\theta_0 U(1 - s_0(\theta^0)) + \tilde{\theta}_0 U(s_0(\theta^0)) + \delta W(\theta^0)]. \tag{22}
\]

Constraint (22) is often referred to as a threat-keeping constraint. This constraint says that if \( \theta_{-1} \) is equal to \( \theta^{-1} \) as opposed to \( \theta^t \), the expected welfare under the savings rate sequence that solves the program must be equal to \( V \). Using this formulation, we rewrite program (12) recursively as follows:

\[
W(\theta^i, V^i) = \max_{\{s^L, s^H, V^L, V^H\}} \left\{ p(\theta^L | \theta^i)(\theta^L U(1 - s^L) + \tilde{\theta}^L U(s^L) + \delta W(\theta^L, V^L)) + p(\theta^H | \theta^i)(\theta^H U(1 - s^H) + \tilde{\theta}^H U(s^H) + \delta W(\theta^H, V^H)) \right\} \tag{23}
\]

\[
\text{s.t.} \quad 
\begin{align*}
\theta^L U(1 - s^L) + \beta \tilde{\theta}^L U(s^L) + \beta \delta W(\theta^L, V^L) &\geq \theta^L U(1 - s^H) + \beta \tilde{\theta}^H U(s^H) + \beta \delta V^H, \\
\theta^H U(1 - s^H) + \beta \tilde{\theta}^H U(s^H) + \beta \delta W(\theta^H, V^H) &\geq \theta^H U(1 - s^L) + \beta \tilde{\theta}^L U(s^L) + \beta \delta V^L,
\end{align*} \tag{24}
\]

\[
V^L \leq V^i \leq V^L, \text{ and } V^H \leq V^t \leq V^H. \tag{27}
\]

(23)–(27) is a recursive representation of (12) starting from some history \( \theta^{t-1} \). The program selects savings rates \( s^i \) for \( i \in \{L, H\} \)—which represent the values of \( s_t(\theta^t) \)—and threats \( V^i \) for \( i \in \{L, H\} \)—which represent the values of \( V_{t+1}(\theta^t) \)—to maximize social welfare, taking into account that the continuation welfare conditional on \( \theta_t = \theta^t \) is equal to \( W(\theta^t, V^i) \), and subject to (24)–(27). Constraint (24) is a recursive representation of the threat-keeping constraint stating that if type \( \theta^{-i} \) deviates and pretends to be \( \theta^t \) in period \( t - 1 \), his continuation welfare at \( t \) is equal to \( V \). As such, \( V^i \), which is chosen in the current period \( t \), is the continuation welfare at \( t + 1 \) to a type \( \theta^{-i} \) who pretends to be \( \theta^t \) at \( t \). Constraints (25)–(26) are recursive representations of the incentive compatibility constraints in (11), and constraint (27) guarantees that the values of \( V^i \) are within a feasible range.
We next characterize \( W(\theta^i, V) \). Clearly, if shocks are i.i.d., it must be that \( W(\theta^i, V) = V \). If shocks are persistent, the following lemma holds:

**Lemma 1.** If shocks are persistent, \( W(\theta^i, V) \) is strictly increasing, strictly concave, and continuously differentiable in \( V \) over the range \((V^i, V^i)\).

**Proof.** See Appendix D. \(\square\)

\(V^i\) and \(V^i\) are respectively the lowest and highest values of \( V_{t+1}(\theta^t) \) that can be attained in the solution to (12). \(V^i\) is the value of \( V \) that results from the sequence problem (12) given \( \theta_{-1} = \theta^i \) and subject to the threat-keeping constraint (22) when this constraint does not bind, so that the solution effectively corresponds to the ex-ante optimum. Values of \( V_{t+1}(\theta^t) \) that exceed \( V^i \) are never attained along the equilibrium path: such high values of \( V_{t+1}(\theta^t) \) would tighten the incentive compatibility constraints (25) and (26) while simultaneously reducing the continuation welfare below \( W(\theta^i, V^i) \). Hence, only threats such that \( V^i < V^i \) are used, and the optimal level of threats depends on the benefits of relaxing incentive compatibility constraints relative to the costs of reducing continuation welfare \( W(\theta^i, V^i) \).

To understand the role of Assumption 2 and the threat-keeping constraint (24), let \( \lambda \) be the Lagrange multiplier on this constraint. The envelope condition implies \( W_V(\theta^i, V) = -\lambda \), so that given the strict concavity of \( W(\cdot) \), lower values of \( V \) are associated with more negative values of \( \lambda \). It follows that solving (23)–(27) is equivalent to solving the following problem:

\[
\max_{\{s_L, s_H, V^L, V^H\}} \left\{ \begin{array}{l}
(p(\theta^L|\theta^i) + \lambda p(\theta^L|\theta^{-i}))(\theta^L U(1 - s^L) + \tilde{\theta}^L U(s^L) + \delta W(\theta^L, V^L)) \\
+(p(\theta^H|\theta^i) + \lambda p(\theta^H|\theta^{-i}))(\theta^H U(1 - s^H) + \tilde{\theta}^H U(s^H) + \delta W(\theta^H, V^H))
\end{array} \right\}
\text{s.t. (25) – (27).}
\]

Under persistent types, the role of the threat-keeping constraint is to effectively “twist” the probabilities assigned to each type. If, for example, \( \theta^i = \theta^H \), the objective in (28) under-weighs welfare conditional on the low type relative to the high type, and this is done more severely the lower is \( V \). The opposite is true if \( \theta^i = \theta^L \). Hence, to satisfy the threat-keeping constraint, the program over-weighs (under-weighs) welfare at \( t \) conditional on the type that is less (more) likely to occur from the perspective of a deviating type \( \theta^{-i} \) at \( t-1 \).

Assumption 2 facilitates the characterization of \( W(\theta^i, V) \) because it guarantees that, along the equilibrium path, the value of \( V \) is never chosen to be so low that the objective in (28) would assign a negative weight to some type.\(^{37}\) Intuitively, if \( V \) is very low, then types are sufficiently close that any benefits from providing better incentives today are outweighed by the costs of reduced welfare tomorrow. Note that these relative benefits and costs depend on

\(^{37}\)In the case that the objective assigns a negative weight to a type, we are not able to prove that \( W(\theta^i, V) \) is concave and differentiable, which prevents us from achieving a characterization of the equilibrium dynamics.
the persistence of types; in particular, under a high level of persistence \( p(\theta^i|\theta^i) \), the future welfare costs may be incurred by a type that is unlikely to occur. This explains why the condition in Assumption 2 depends on \( p(\theta^i|\theta^i) \). (See Lemma 8 in Appendix D for details.)

5.2.2 Characterization

We now characterize the ex-ante optimal fiscal rule. Consider first the i.i.d. benchmark.

**Proposition 2 (ex-ante optimum under i.i.d. shocks).** If shocks are i.i.d., the ex-ante optimum coincides with the sequential optimum.

*Proof. See Appendix D.*

When shocks are i.i.d., the ex-ante optimal rule prescribes the sequentially optimal savings rate in each period, which in this case is constant and which can be implemented with a renegotiated debt limit. This rule is thus history independent and does not provide dynamic incentives for truthtelling. The reason why dynamic incentives are inefficient is as discussed in the three-period example: under i.i.d. shocks, any perturbation in the ex-post optimal rule affects continuation welfare on the equilibrium path (given a truthful report) and off the equilibrium path (given a non-truthful report) equally, and therefore cannot increase ex-ante welfare. This result is analogous to that of Amador, Werning, and Angeletos (2006).

Consider now the case of persistent shocks. Let the solution to (23)–(27) be denoted by

\[
\{s^L_*(\theta^i, V), s^H_*(\theta^i, V), V^L_*(\theta^i, V), V^H_*(\theta^i, V)\}.
\]

**Lemma 2.** If shocks are persistent, the solution to (23)–(27) has the following properties for all \( V \in [V^L, V^H] \):

(i) **(resetting)** \( V^L_*(\theta^i, V) = V^L \) for \( \theta^i \in \{\theta^L, \theta^H\} \);

(ii) **(monotonicity of threats)** \( V^H_*(\theta^H, V) \) is strictly decreasing in \( V \) and \( V^H_*(\theta^i, V) \) satisfies \( V^H > V^H_*(\theta^H, V^H) > V^H_*(\theta^L, V^L) \);

(iii) **(monotonicity of savings rates)** \( s^i_*(\theta^H, V) \) is strictly increasing in \( V \) and \( s^i_*(\theta^i, V) \) satisfies \( s^i_*(\theta^H, V^H) < s^i_*(\theta^L, V^L) \) for \( i \in \{L, H\} \).

*Proof. See Appendix D.*

**Lemma 2** describes the solution to (23)–(27) given \( \theta^i \) and \( V \). The first part of the lemma states that the equilibrium at \( t + 1 \) effectively “resets” if the low type is realized at \( t \). This result is analogous to the result in the three-period example that the savings rate at date 1 is sequentially optimal if the low type is realized at date 0. As in that example, the intuition
is that setting $V^{L*}(\theta^i, V) = \overline{V}^L$ maximizes the continuation payoff of the low type given a truthful report, and thus maximally relaxes the incentive compatibility constraint of the low type (25) while maximizing social welfare.

The second part of Lemma 2 concerns the magnitude of $V^{H*}(\theta^i, V)$ across different values of $V$. Comparing $V^{H*}(\theta^H, \overline{V}^H)$ and $V^{H*}(\theta^L, \overline{V}^L)$, the lemma states that the threat used in the ex-ante optimum to induce the low type to report truthfully is more severe if $\theta^i = \theta^L$ than if $\theta^i = \theta^H$. This result is analogous to the result in the three-period example that the savings rate at date 1 following $\theta_0 = \theta^H$ is lower if $\theta_{-1} = \theta^L$ than if $\theta_{-1} = \theta^H$. The intuition is also as in that example: when $\theta^i = \theta^L$, the low shock is more likely, so the benefit of using a more severe threat—namely, relaxing the low type’s incentive constraint and curbing his spending—is larger relative to the cost—namely, reducing the high type’s continuation welfare. The lemma also considers how $V^{H*}(\theta^H, V)$ varies with $V$. As discussed, the lower is $V$, the more “twisted” the effective objective function in (28) is in favor of welfare conditional on a high type, implying that threats are more costly and thus $V^{H*}(\theta^H, V)$ is higher.

The third part of Lemma 2 considers how the optimal savings rate depends on $V$. Comparing $s^{i*}(\theta^H, \overline{V}^H)$ and $s^{i*}(\theta^L, \overline{V}^L)$, the lemma states that the savings rate conditional on the realization of either type is lower if $\theta^i = \theta^H$ than if $\theta^i = \theta^L$. The intuition is straightforward. Because of Assumption 2, the savings rate of the low (high) type is always below (above) the first-best rate for that type. If $\theta^i = \theta^H$, the objective function in (28) puts a higher weight on welfare conditional on a high type, so the optimal savings rate for this type must be lower and closer to first best. But then for the incentive constraint of the low type (25) to be satisfied, it must be that the savings rate of the low type is also lower, implying that $s^{i*}(\theta^H, \overline{V}^H) < s^{i*}(\theta^L, \overline{V}^L)$ for $i \in \{L, H\}$. The lemma also compares $s^{i*}(\theta^H, V)$ across different values of $V$. The logic is the same as above: the lower is $V$, the higher is the weight in (28) assigned to the high type and, consequently, the lower is $s^{i*}(\theta^H, V)$.

We now use Lemma 2 to describe the ex-ante optimal fiscal rule under persistent shocks. Define $\eta_l(\theta^{l-1})$ as the number of periods since the last time that $\theta^L$ was realized:

$$\eta_l(\theta^{l-1}) = k \text{ if } \theta_{t-1-k} = \theta^L \text{ and } \theta_{t-1-l} = \theta^H \text{ for all } l \in \{0, \ldots, k - 1\}.$$ 

Proposition 3 (ex-ante optimum under persistent shocks). If shocks are persistent, the ex-ante optimum has the following features:

(i) For all $\theta^l$ and $\theta^k$ with $\theta_t = \theta_k$, $s_t(\theta^l) = s_k(\theta^k)$ if $\eta_t(\theta^{t-1}) = \eta_k(\theta^{k-1})$;

(ii) There exist $\theta^l, \theta^k$ with $\theta_t = \theta_k$ and $\theta_{t-1} = \theta_{k-1}$ for which $s_t(\theta^l) \neq s_k(\theta^k)$.

Thus, the ex-ante optimum does not coincide with the sequential optimum, and it exhibits history dependence.
Unlike the sequentially optimal rule or the optimal rule under i.i.d. shocks, the ex-ante optimal rule under persistent shocks exhibits history dependence: the mechanism at history $\theta^t$ depends not only on the payoff-relevant variables, $\theta_{t-1}$ and $b_t(\theta^{t-1})$, but also on when the low shock last occurred, and thus possibly on the entire history of shocks. The logic stems from the fact that the mechanism provides dynamic incentives. Intuitively, because the shock at date $t-2$ predicts the realization of the shock at $t-1$, the shock at $t-2$ affects the relative tightness of incentive compatibility constraints at $t-1$, which in turn affect the policies that are chosen at $t$ in providing dynamic incentives at $t-1$. The result in Lemma 2 that the mechanism resets following a low shock implies in fact that the tightness of current incentive constraints depends on when this resetting began, which explains why prescribed policies depend on the time that passed since a low shock was realized.

The resetting property of the ex-ante optimal rule is related to the “no distortion at the top” result of standard static adverse selection models as well as dynamic models such as Battaglini (2005). In our framework, the lack of cross-subsidization across types implies that maximizing the reward to the low type who tells the truth does not have any direct resource costs for the high type. Maximizing this reward by resetting the mechanism is then optimal as it allows to maximally relax incentive constraints. To see this, consider an equilibrium starting from date 0. If $\theta_0 = \theta^L$, as explained, the equilibrium at date 1 optimally transitions to the ex-ante optimum associated with $\theta_{-1} = \theta^L$. If instead $\theta_0 = \theta^H$, the fiscal rule at date 1 seeks to punish the low type at date 0 who would have lied, while not harming the truthful high type too much. There are two ways in which this can be done: first, spending at date 1 given a low type at date 1 can be made higher and further away from first best; second, the expected continuation welfare at date 1 from date 2 onward, given a low type at date 1, can be made lower. Because the low type at date 0 is more likely to be a low type at date 1, either of these changes hurts the deviating low type at date 0 more than the truthful high type at date 0. However, while the first option slackens the low type’s incentive constraint at date 1, the second option tightens this constraint. Consequently, it is cheaper from a date 0 perspective to provide incentives to the low type by increasing spending for a single period following a high shock, while resetting the equilibrium thereafter given a low shock.

Under the ex-ante optimal rule, high shocks then lead to an erosion of future fiscal discipline compared to low shocks, which lead to the reinstatement of discipline. A natural question regards the equilibrium dynamics for a sequence of consecutive high shocks. These can be described using the second and third parts of Lemma 2, as shown in the following proposition.

---

38It is straightforward to show that for histories for which the low shock has never realized (for which $\eta_t(\theta^{t-1})$ is not defined), policies are history dependent in the sense that they are a function of the date $t$. 

---
Proposition 4 (dynamics under persistent shocks). There exists $\hat{V}$ such that for all $\theta^t$, if $\theta_{t-1} = \theta_t = \theta^H$, then $V_{t+1}(\theta^t) > (\prec) \hat{V}$ if $V_t(\theta^{t-1}) < (\succ) \hat{V}$. Thus, the ex-ante optimum features oscillations in savings rates.

Proof. See Appendix D.

Combined with Lemma 2, Proposition 4 states that under a sequence of consecutive high shocks, the equilibrium oscillates between periods of high spending and periods of low spending, around some fiscal rule associated with a threat $\hat{V}$ such that $V^H(\theta^H, \hat{V}) = \hat{V}$. In all of these periods, there is a lack of fiscal discipline in that the level of spending exceeds the level under $\theta^t = \theta^H$, $V = V^H$.

To understand the oscillatory dynamics, consider again the equilibrium starting from date 0, given $\theta_{-1} = \theta^H$. As explained, if $\theta_0 = \theta^H$ is realized at date 0, the ex-ante optimal rule induces high spending at date 1 given a low type at date 1, where this spending is further away from first best compared to spending at date 0 given a low type at date 0. It follows that at date 1, the low type’s incentives to lie and pretend to be a high type are relatively lower, and, in turn, a smaller threat at date 2 following a high type at date 1 is sufficient to provide incentives at date 1. Yet, note that the equilibrium does not reset to the ex-ante optimum at date 2; the reason is simply that if spending at date 2 corresponded to the ex-ante optimal spending level given $\theta_{-1} = \theta^H$, incentive compatibility constraints at dates 0 and 1 could be relaxed by increasing such spending, implying a first-order gain and causing only a second-order loss at date 2.

The economics behind the oscillatory dynamics in Proposition 4 emerge from the self-control nature of the problem. The absence of discipline tomorrow is used to induce discipline today. In turn, the absence of discipline tomorrow allows to increase discipline the day after while preserving incentives tomorrow. Because the time inconsistency problem lasts a single period in our setting, the oscillations under a sequence of consecutive high shocks are also each a single period long. Recall that under the political turnover interpretation of our preferences (see Section 2), our formulation corresponds to political cycles lasting one period; however, it is clear that the results are robust to different political turnover frequencies so long as these coincide with the frequency of economic shocks. Specifically, in a setting where turnover occurs every $N$ periods and economic shocks also occur every $N$ periods, our analysis would imply the presence of $N$-period oscillations. A related question concerns the form that oscillations exhibit: during consecutive periods of high shocks, public spending under the ex-ante optimal rule exhibits higher volatility than that implied by the shock process, and thus higher volatility than under the sequentially optimal rule or the first-best policy. The oscillatory dynamics may imply convergence towards the fiscal rule associated with $V = \hat{V}$, although this depends on the slope of the policy function. While we cannot characterize the slope of this policy function analytically, numerical simulations suggest that convergence towards $V = \hat{V}$ indeed occurs in equilibrium.\footnote{This implies that, during consecutive periods of high shocks, public spending under the ex-ante optimal rule exhibits higher volatility than that implied by the shock process, and thus higher volatility than under the sequentially optimal rule or the first-best policy. The oscillatory dynamics may imply convergence towards the fiscal rule associated with $V = \hat{V}$, although this depends on the slope of the policy function. While we cannot characterize the slope of this policy function analytically, numerical simulations suggest that convergence towards $V = \hat{V}$ indeed occurs in equilibrium.}
would take if political turnover and economic shocks occurred at different frequencies; such an environment however would involve quite distinct considerations.\footnote{For the case where political turnover occurs every $N$ periods while economic shocks occur at a higher frequency, our preliminary analysis suggests that under some conditions the economy experiences oscillations in an $N$-period contract every $N$ periods, so that oscillations again reflect the frequency of turnover. If political turnover occurs instead at a higher frequency than economic shocks, additional complications are introduced because the full persistence of shocks across periods of turnover implies that the full support assumption no longer holds.}

### 5.2.3 Implementation

In our analysis of the sequentially optimal rule in Subsection 5.1, we showed that such a rule can be implemented with a history-independent debt limit. That is, in each period, the government is allowed to borrow any amount up to some threshold, where this threshold depends only on the accumulated level of debt and the previous period’s shock.

A possible implementation of the ex-ante optimal rule is also with the use of debt limits, although, importantly, these limits would now depend on the history. In particular, in the ex-ante optimum, the level of debt that the government is allowed to incur in any period would depend not only on how much the government borrowed up to that period (i.e., the current level of debt), but also on how much the government chose to borrow relative to debt limits in previous periods.

More specifically, the ex-ante optimal rule can be implemented as follows. In each period, the government is subject to two debt limits: a low debt limit that corresponds to the level of debt incurred under the low shock and a high debt limit that corresponds to the level of debt incurred under the high shock. The low debt limit can be seen as the limit that would prevail in “normal times”, while the high debt limit applies if the government decides to utilize an “escape clause” to exceed the low limit up to some point.\footnote{Debt limits combined with escape clauses are a common form of fiscal rules across the world; see International Monetary Fund (2009).} From Proposition 3, it is clear that these two limits depend not only on the payoff-relevant variables, the level of debt and the previous period’s shock, but also on $\eta_t$, namely the number of periods that have passed since normal times last prevailed. Under this implementation, periods of non-discipline are those that occur after escape clauses are triggered, while periods of discipline emerge once escape clauses stop being utilized.

It is worth noting here that we have considered throughout an environment where the government has the ability to commit within the period to a fiscal rule. In the implementation of the ex-ante optimal rule just described, this means that even if an escape clause is utilized to exceed the low debt limit, the government is committed to not go beyond the high debt limit. A natural question is whether, in the absence of commitment power, such a debt limit—and more generally the dynamic fiscal rule—can be self-enforced. Using standard folk theorems,
one can show that the ex-ante optimal rule can indeed be self-enforced if society’s discount factor ($\delta$) is high enough. This follows from the fact that, in each period, equilibrium social welfare in the ex-ante optimum is strictly higher than welfare when the government is granted full flexibility to choose fiscal policy; thus, self-enforcement can be achieved by using the threat of reversion to full flexibility upon deviations from the prescribed policies.\footnote{By analogous reasoning, self-enforcement of the sequentially optimal fiscal rule is also possible. An interesting question for future research is how self-enforcement can be achieved when the discount factor is not sufficiently high. Bernheim, Ray, and Yeltekin (2013) characterize the worst “punishment” that can be imposed upon a deviation to self-enforce commitment contracts in a related environment without private information.} In terms of the implementation above, this means that any violation of the high debt limit—which never occurs along the equilibrium path—would result in the permanent abandonment of fiscal rules.

5.3 Implications for Debt in the Long Run

The analysis of the previous sections shows that the savings rates induced by the ex-ante optimal and sequentially optimal rules differ when shocks are persistent. What are the implications for the path of debt? Do these rules imply different levels of debt in the long run?

To characterize the debt dynamics, we consider the case where the market discounts the future at the same rate as the government (prior to the realization of the shock):\footnote{We focus on this case for simplicity. An analogous analysis of the forces that push debt to increase or decrease in the long run can also be performed by considering the interest rate that guarantees a non-degenerate long-run level of debt.}

$$\delta = \frac{1}{1 + r}. \quad (30)$$

For any sequence of savings rates $s_t$, $t \in \{0, 1, \ldots\}$, that admits a long-run ergodic distribution, let $\bar{s}$ be the mean of $\log(s_t/\delta)$ in this distribution. The following result will be useful to characterize debt dynamics under different policies.

**Lemma 3.** Assume (30) holds. If $\bar{s} > 0$, assets diverge to infinity: $b_t \to -\infty$ as $t \to \infty$. If $\bar{s} < 0$, debt becomes maximal: $b_t \to \tau/(1 - \delta)$ as $t \to \infty$.

Consider now the path of debt under the first-best and full-flexibility policies. The first-best savings rates satisfy $s_t^{fb} = s_t^{fb}(\theta^i)$ if $\theta_t = \theta^i$, where $s_t^{fb}(\theta^i)$ is defined in (8). The full-flexibility savings rates satisfy $s_t^f = s_t^f(\theta^i)$ if $\theta_t = \theta^i$, where for $\theta^i \in \{\theta^L, \theta^H\}$,\footnote{Multiple equilibria can emerge when the government is given full flexibility in every period. Analogous to our selection of the sequential optimum, we select a unique solution by considering the limit of a finite horizon economy with end date $T$ as $T$ approaches infinity.}

$$\theta^i U'(1 - s^f(\theta^i)) = \beta \theta^i U'(s^f(\theta^i)). \quad (31)$$
Using Lemma 3, we show that, as may be expected, the debt dynamics under these two policies are starkly different.

**Lemma 4.** Assume (30) holds.

(i) Under first best, \( \bar{s}^{fb} > 0 \), so assets diverge to infinity;

(ii) Under full flexibility, \( \bar{s}^f < 0 \), so debt becomes maximal.

*Proof.* See Appendix E. \( \square \)

The intuition for the first part of Lemma 4 stems from the self-insurance motive of the government. As is common across a wide class of self-insurance models (e.g., Chamberlain and Wilson, 2000), when condition (30) holds, this motive dominates in the long run, and the first-best policy for the government is to accumulate enough assets to perfectly insure itself with an infinite level of public spending. The second part of Lemma 4, however, shows that if given the option to flexibly choose policy, a present-biased government would not engage in such an accumulation of infinite assets. To the contrary, the government’s present bias would cause the economy to accumulate the maximal amount of debt in the long run, pushing public spending towards zero. This stark contrast between the first-best and full-flexibility economies highlights the importance of fiscal rules to alleviate the government’s time inconsistency problem.

Consider next the path of debt under the sequentially optimal rule as characterized in Proposition 1.

**Proposition 5 (long-run debt in sequential optimum).** Assume (30) holds. In the sequentially optimal rule,

(i) Under i.i.d. shocks, \( \bar{s}^{so} = 0 \) and the level of debt is constant;

(ii) Under persistent shocks, \( \bar{s}^{so} > 0 \), so assets diverge to infinity.

*Proof.* See Appendix E. \( \square \)

In the sequential optimum, the government commits at date \( t-1 \) to a savings rate at date \( t \). If shocks are i.i.d., the savings rate at \( t \) is independent of the government’s information at \( t-1 \) and therefore constant over time. In fact, using condition (21), this rate is equal to the discount factor \( \delta \), and hence, given (30), the level of debt is also constant over time. In contrast, when shocks are persistent, the savings rate at date \( t \) depends on the information that the government has at \( t-1 \). In particular, if \( \theta_{t-1} = \theta^L \) is realized, the government anticipates lower spending needs at \( t \), and thus commits to saving more at \( t \) to insure itself for the future. Analogous to the first-best case above, it is this self-insurance motive, combined with (30), what makes the government eventually accumulate an infinite amount of assets.
Finally, we consider the path of debt under the ex-ante optimal rule. The savings rates in the ex-ante optimum are characterized by Proposition 2 when shocks are i.i.d. and by Proposition 3 when shocks are persistent. Note that from Proposition 3, the savings rate at date $t$ under persistent shocks is a function only of the current shock and the number of periods since the last low shock. Let $s^{eo}(\theta^i, \eta)$ be the savings rate when the current shock is $\theta^i$ and the number of periods since $\theta^L$ was last realized is $\eta \geq 0$. It follows that:

$$
\bar{s}^{eo} = \frac{1}{2} \left[ p(\theta^i|\theta^i) \log(s^{eo}(\theta^L, 0)/\delta) + (1 - p(\theta^i|\theta^i)) \log(s^{eo}(\theta^H, 0)/\delta) \right] 
$$

$$
+ \frac{1}{2} (1 - p(\theta^i|\theta^i)) \sum_{k=1}^{\infty} p(\theta^i|\theta^i)^{k-1} \left[ p(\theta^i|\theta^i) \log(s^{eo}(\theta^H, k)/\delta) + (1 - p(\theta^i|\theta^i)) \log(s^{eo}(\theta^L, k)/\delta) \right].
$$

Using Lemma 3, the following result obtains.

**Proposition 6 (long-run debt in ex-ante optimum).** Assume (30) holds. In the ex-ante optimal rule,

(i) Under i.i.d. shocks, $\bar{s}^{eo} = 0$ and the level of debt is constant;

(ii) Under persistent shocks, both $\bar{s}^{eo} > 0$ and $\bar{s}^{eo} < 0$ hold for an open set of parameters $\{\theta^L, \theta^H, p(\theta^i|\theta^i), \delta, \beta\}$ satisfying Assumption 2, so assets may diverge to infinity or debt may become maximal depending on parameters.

**Proof.** See Appendix E. \qed

If shocks are i.i.d., the ex-ante optimal and sequentially optimal rules coincide, so it follows from Proposition 5 that debt is constant. If instead shocks are persistent, the long-run path of debt in the ex-ante optimum may entail accumulating infinite assets or maximal debt, depending on parameters. The intuition stems from the interaction of two countervailing forces. On the one hand, there is an operational precautionary motive that pushes the government towards the accumulation of assets, just as in the first best and the sequential optimum. On the other hand, the ex-ante optimum features the provision of dynamic incentives, whereby phases of non-discipline along the equilibrium path are used to sustain discipline in earlier periods. These phases of non-discipline push the government towards the accumulation of debt, and can dominate the self-insurance motive if they involve sufficiently low savings rates. Therefore, while the ex-ante optimal rule yields higher ex-ante welfare than the sequentially optimal rule, it can induce the government to become immiserated in the long run, just as under full flexibility.\(^46\)

\(^45\)See Appendix E for details.

\(^46\)A similar force towards immiseration arises in the principal-agent models of Atkeson and Lucas (1992).
Figure 3: Path of debt in the ex-ante and sequentially optimal rules with $\delta = \frac{1}{1+r}$, $\beta'' > \beta'$.

To illustrate, we consider economies with different ex-ante optimal debt dynamics. Figure 3 depicts two economies which differ in their degrees of time inconsistency. As discussed in the three-period example of Section 4, the government’s present bias affects the extent to which the ex-ante optimal rule provides dynamic incentives: the larger this bias is, the less effective is the threat of future non-discipline to provide incentives in the present, and thus the lower are the incentives that are optimally given. As a result, the figure shows that when the government’s present bias is relatively large (that is, $\beta$ is low), incentives are low and the self-insurance motive dominates, so $\bar{s}_o > 0$ and the government accumulates infinite assets over time. Instead, when the government’s present bias is relatively small (that is, $\beta$ is high), the ex-ante optimal mechanism provides strong dynamic incentives, so periods of

and Thomas and Worrall (1990). As in our model, this force emerges as a consequence of dynamic incentive provision. However, note that those papers consider i.i.d. shocks, whereas in our self-control setting dynamic incentives are provided only when shocks are persistent. Moreover, in our model, dynamic incentives need not always result in immiseration, as the countervailing self-insurance motive pushes towards asset accumulation.

47 We consider $\theta^L = 2$, $\theta^H = 3$, $p(\theta^i | \theta^j) = 0.55$, $\delta = 0.7$, $\beta' = 0.01$, $\beta'' = 0.4$, $b_0 = 0$, $r = 1$. Recall that the sequential optimum is independent of $\beta$. For the ex-ante optimum, the comparison across different values of $\beta$ takes into account that, given other parameters, $\beta$ must be low enough for Assumption 2 to be satisfied. To compute the equilibrium, we use the fact that there is a one-to-one mapping between $\lambda$ in (28) and the threat value $V$ in (23), so that the value function depends on last period’s shock and $\lambda$. For a given $\lambda$, the value of the Lagrange multiplier on the incentive constraint implies savings rates from the first-order conditions. Moreover, first-order conditions also imply that the value of $\lambda'$ for the next period depends only on $\lambda$ and this Lagrange multiplier. We therefore guess an initial value function of $\lambda$ and for each $\lambda$ we find a value of the Lagrange multiplier that makes the incentive constraint bind. We then feed this value and $\lambda$ together with the implied savings rates and $\lambda'$ back into the construction of the value function until the value function converges.
non-discipline are severe enough that $\bar{s}^{eo} < 0$ and the government becomes immiserated in the long run. Analogous comparative statics can be obtained for other parameters. For example, using computational methods, we find that $\bar{s}^{eo}$ is non-monotonic in the persistence of shocks, $p(\theta^i|\theta^t) \in [0.5, 1)$. Mirroring our results for the three-period economy, the relationship between $\bar{s}^{oe}$ and $p(\theta^t|\theta^i)$ is $U$-shaped, so that debt is more likely to become maximal in the long run for intermediate values of $p(\theta^t|\theta^i)$.\footnote{Additionally, one can show that in the cases where (30) does not hold, immiseration is more likely to occur if the exogenous interest rate $r$ is low.}

6 Concluding Remarks

This paper has studied the role of persistence in determining the optimal structure of fiscal rules. We showed that when the shocks to the economy are i.i.d., the ex-ante optimal fiscal rule coincides with the sequentially optimal rule, taking the simple form of a renegotiated debt limit. In contrast, when the shocks are persistent, the ex-ante optimal rule is no longer sequentially optimal; this rule now provides dynamic incentives and exhibits history dependence. The ex-ante optimal mechanism features rich dynamics, with high shocks leading to an erosion of future fiscal discipline while low shocks reinstate discipline, and with policy distortions oscillating over time given a sequence of high shocks. Moreover, while the sequentially optimal rule leads to the accumulation of infinite assets over time, the ex-ante optimal rule may induce the government to accumulate maximal debt and become immiserated in the long run.

We believe our paper leaves interesting questions for future research. One possible extension would be to consider more general time-inconsistent preferences with hyperbolic discounting. The nature of the problem would change compared to our quasi-hyperbolic setting, as the preferences of the current government regarding future policies would no longer coincide with those of society. As the government’s bias extends to future periods, in fact, the problem becomes one of delegation. Also, our model can be enriched to consider more general social preferences for public spending, as well as a micro-founded economic environment taking into account the endogeneity of interest rates and the distortionary effects of taxation. A natural future direction would be to quantitatively assess the properties of optimal fiscal rules and how they depend on the economic structure.

While we have focused on fiscal policy, the insights of this paper can be applied to other settings as well. First, our setup can be naturally applied to individual self-control problems, including those related to decisions such as how much to consume, how much to drink, how often to go to the gym, how much to smoke, etc. In those contexts, an individual has a temptation to renege on commitments made to oneself ex ante, and rules can help improve welfare. Second, our model may have implications for other organizations where leaders rotate
in and out of power, such as committees within firms or academic departments. Leaders in these settings may be tempted to overspend when they hold the purse strings, but not when they do not. Finally, a monetary authority also faces a tradeoff between commitment and flexibility, and some of the results from our fiscal policy model can be applied to monetary policy.\footnote{Athey, Atkeson, and Kehoe (2005) consider the commitment versus flexibility tradeoff in a monetary policy model with i.i.d. shocks.}
Appendix

A Deriving the Sequentially Optimal Rule

In this appendix, we consider the problem defined by (13)–(15) for a finite horizon $T$-period economy and show that as $T \to \infty$, this program is equivalent to (16)–(17).

Define

$$J_T^T (\theta_{T-1}, b_T) = \sum_{\theta_T \in \{\theta^L, \theta^H\}} p(\theta_T | \theta_{T-1}) \theta_T U(\tau - b_T) \quad (A.1)$$

as the expected social welfare at date $T$ conditional on $\theta_{T-1}$ and $b_T$, given the budget constraint (1) and given the end date $T$. Using $J_T^T (\theta_{T-1}, b_T)$, define the sequential optimum recursively as a solution to:

$$J_t^T (\theta_{t-1}, b_t) = \max_{\{g_t(\theta_t), b_{t+1}(\theta_t)\}_{\theta_t \in \{\theta^L, \theta^H\}} \theta_t \in \{\theta^L, \theta^H\}} \sum_{\theta_t \in \{\theta^L, \theta^H\}} p(\theta_t | \theta_{t-1}) (\theta_t U(g_t(\theta_t)) + \delta J_{t+1}^T (\theta_t, b_{t+1}(\theta_t))) \quad (A.2)$$

subject to

$$g_t(\theta_t) = \tau + b_{t+1}(\theta_t) / (1 + r) - b_t$$

and

$$\theta_t U(g_t(\theta_t)) + \beta \delta J_{t+1}^T (\theta_t, b_{t+1}(\theta_t)) \geq \theta_t U(g_t(\theta_t)) + \beta \delta J_{t+1}^T (\theta_t, \tilde{b}_{t+1}(\theta_t)) \text{ for } \tilde{\theta}_t \neq \theta_t. \quad (A.3)$$

The only difference between (13)–(15) and (A.2)–(A.4) is that the latter takes into account the finite horizon, with $J_t^T (\theta_{t-1}, b_t)$ being welfare at $t$ conditional on the end date $T$.

For $t < T$, define $\tilde{\theta}_t^T$ analogously to (4):

$$\tilde{\theta}_t^T = \sum_{k=1}^{T-t} \delta^k \mathbb{E}[\theta_{t+k} | \theta_t],$$

where it is clear that $\lim_{T \to \infty} \tilde{\theta}_t^T = \tilde{\theta}_t$, for $\tilde{\theta}_t$ defined in (4).

With some abuse of notation, define the finite horizon savings rate analogously to (5):

$$g_t(\theta_t) = (1 - s_t(\theta_t))((1 + r)^{T-t+1} - 1)/(r (1 + r)^{T-t}) - b_t,$$

where $s_T(\theta_T) = 0$. We now show that, given $T$, the program defined in (A.2)–(A.4) for any $t$ is equivalent to

$$\max_{\{s_t(\theta_t)\} \theta_t \in \{\theta^L, \theta^H\}} \sum_{\theta_t \in \{\theta^L, \theta^H\}} p(\theta_t | \theta_{t-1}) (\theta_t U(1 - s_t(\theta_t)) + \tilde{\theta}_t^T s_t(\theta_t))) \quad (A.5)$$

subject to

$$\theta_t U(1 - s_t(\theta_t)) + \beta \tilde{\theta}_t^T U(s_t(\theta_t)) \geq \theta_t U(1 - s_t(\theta_t)) + \beta \tilde{\theta}_t^T U(s_t(\theta_t)) \text{ for } \tilde{\theta}_t \neq \theta_t. \quad (A.6)$$

We show this by induction. First note that (A.2)–(A.4) is equivalent to (A.5)–(A.6) for
\( t = T - 1 \). This follows from the fact that \( J_T^T (\theta_{T-1}, b_T) \) satisfies

\[
\delta J_T^T (\theta_{T-1}, b_T) = \tilde{\theta}_{T-1}^T U (s_{T-1} (\theta_{T-1})) + \chi_{T-1}^T (b_{T-1}),
\]

(A.7)

for some constant \( \chi_{T-1}^T (b_{T-1}) \) which depends only on \( b_{T-1} \). Substitution of (A.7) into the program (A.2)–(A.4) at \( t = T - 1 \) implies that (A.2)–(A.4) is equivalent to (A.5)–(A.6) at \( t = T - 1 \). Moreover, it also implies that

\[
\delta J_{T-1}^T (\theta_{T-2}, b_{T-1}) = \tilde{\theta}_{T-2}^T U (s_{T-2} (\theta_{T-2})) + \chi_{T-2}^T (b_{T-2}),
\]

(A.8)

for some constant \( \chi_{T-2}^T (b_{T-2}) \) which depends only on \( b_{T-2} \). Taking (A.8) into account, forward iteration of this reasoning implies that (A.2)–(A.4) is equivalent to (A.5)–(A.6) for all \( t \). Taking \( T \to \infty \), it is clear that (A.5)–(A.6) converges to (16)–(17), completing the argument.

## B Extension to Continuum of Shocks

In this appendix, we extend our analysis to a setting with a continuum of shocks. We consider this setting not only to explore the robustness of our main results, but also because economies with a continuum of shocks are the main focus of the mechanism design literature that studies the tradeoff between commitment and flexibility.

The main complication that emerges in this extension is that, under multiple shocks, one must ensure that not only local but also global incentive compatibility constraints are satisfied. This does not complicate the analysis of the sequential optimum, as under log utility that problem reduces to a two-period problem. However, this does complicate the analysis of the ex-ante optimum, as the recursive method described in Subsection 5.2.1 of the paper no longer applies. Nonetheless, we show in this appendix that the main insights from the economy with two shocks continue to hold under a continuum of shocks.

### B.1 Environment

Consider the benchmark environment described in Section 2 but with the government’s type, \( \theta_t > 0 \), now being drawn from a continuous support \( \Theta \equiv [\underline{\theta}, \bar{\theta}] \). Let \( p(\theta_t | \theta_{t-1}) \) and \( \tilde{\theta}_t \) be as previously defined, and assume that \( p(\theta_t | \theta_{t-1}) \) is strictly positive for all \( \theta_t \) and \( \theta_{t-1} \) and continuously differentiable with respect to \( \theta_t \) and \( \theta_{t-1} \). Assumption 3 below, which holds in the two-shock economy, ensures that \( \theta_t \) is mean reverting.

**Assumption 3.** \( \theta_t / \tilde{\theta}_t \) is strictly increasing in \( \theta_t \).

We also make a technical assumption regarding the distribution of shocks. Define \( \theta_p (\theta_{t-1}) = \max \{ \underline{\theta}, \theta' \} \) where \( \theta' \) is the lowest \( \theta \in \Theta \) such that for all \( \theta'' \geq \theta \),

\[
\frac{\tilde{\theta}''}{\underline{\theta}_t \geq \theta''} \frac{E[\theta_t | \theta_t \geq \theta'' , \theta_{t-1}]}{\theta''} \leq \frac{1}{\beta},
\]

(B.1)

---

\(^{50}\)Given this definition, note that the objective function in (A.5) is not exactly identical to (A.2) because we exclude the constant \( \chi_t^T (b_t) \).
where \( \tilde{\theta}' \) is the value of (4) associated with \( \theta_t = \theta'' \). Note that if shocks are i.i.d., \( \theta_p(\theta_{t-1}) = \theta_p \), independent of \( \theta_{t-1} \). Given our assumptions, \( \theta_p(\theta_{t-1}) \) is a continuously differentiable function of \( \theta_{t-1} \). Using this definition, we assume:

**Assumption 4.** For all \( \theta_t \leq \theta_p(\theta_{t-1}) \),

\[
\frac{d \log p(\theta_t|\theta_{t-1})}{d \log \theta_t} \geq -\frac{2 - \beta}{1 - \beta} + \frac{1}{1 - \beta} \frac{d \log \tilde{\theta}_t}{d \log \theta_t} + \frac{d \log(d\tilde{\theta}_t/d\theta_t)}{d \log \theta_t}.
\] (B.2)

Assumption 4 is isomorphic to Assumption A in Amador, Werning, and Angeletos (2006)’s study of an economy with i.i.d. shocks, where the main difference is that our condition incorporates the persistence of shocks through \( d \log \tilde{\theta}_t/d \log \theta_t \) and \( d \log(d\tilde{\theta}_t/d\theta_t)/d \log \theta_t \). This assumption is satisfied if the severity of the time-inconsistency problem is sufficiently low (i.e., \( \beta \) is sufficiently high) and the first and second derivatives of the density function \( p(\theta_t|\theta_{t-1}) \) with respect to both elements are bounded.\(^{51}\)

Definitions for the ex-ante optimal and sequentially optimal fiscal rules analogous to those provided for the two-shock economy apply in this setting. We thus use the analysis of Section 3 to characterize the equilibrium.

### B.2 Sequentially Optimal Rule

An analogous program to (16)–(17) defines the sequentially optimal fiscal rule. The incentive compatibility constraints (17) effectively imply that the problem is static and that global incentive constraints can be ignored. As such, analogous techniques to those used in the analysis of the two-period problem of Amador, Werning, and Angeletos (2006) apply here and can be used to characterize the sequential optimum. Let \( s^f(\theta_t) \) be the flexible optimum of a government of type \( \theta_t \) that is awarded full discretion as defined in (31).

**Proposition 7 (sequential optimum under continuum of shocks).** Let \( \hat{s}(\theta_{t-1}) \) be defined by \( \hat{s}(\theta_{t-1}) = s^f(\theta_p(\theta_{t-1})) \) if \( \theta_p(\theta_{t-1}) \geq \theta \), and

\[
\mathbb{E}[\theta_t|\theta_{t-1}] U'(1 - \hat{s}(\theta_{t-1})) - \mathbb{E}[\hat{\theta}_t|\theta_{t-1}] U'(\hat{s}(\theta_{t-1})) = 0
\] (B.3)

otherwise. For all \( \theta^t \), the sequential optimum features

\[
s_t(\theta^t) = \max\{s^f(\theta_t), \hat{s}(\theta_{t-1})\}.
\]

**Proof.** See the Supplementary Appendix. \( \square \)

**Corollary 2.** The sequentially optimal rule at any date \( t \) can be implemented with a history-independent debt limit, \( \tilde{b}(\theta_{t-1}, b_t(\theta^{t-1})) \).

This proposition and corollary state that if \( \theta_p(\theta_{t-1}) > \theta \), all types \( \theta_t \) below \( \theta_p(\theta_{t-1}) \) are awarded full discretion, so they can choose their flexible optimal savings rate, and all types above \( \theta_p(\theta_{t-1}) \) are awarded no discretion, so they must choose the same savings rate as type \( \theta_p(\theta_{t-1}) \). If instead \( \theta_p(\theta_{t-1}) = \theta \), no type is given discretion, and all types are assigned a savings rate \( \hat{s}(\theta_{t-1}) \) satisfying (B.3).

\(^{51}\)This follows from the fact that, given Assumption 3, \( d \log \hat{\theta}_t/d \log \theta_t < 1 \).
The dependence of the minimum savings rate \( s(\theta_{t-1}) \) on \( \theta_{t-1} \) captures the fact that the shock at date \( t-1 \) provides information regarding the tradeoff between commitment and flexibility at date \( t \). Note that if shocks are i.i.d., \( s(\theta_{t-1}) \) and the associated debt limit \( \bar{b}(\theta_{t-1}, b_t(\theta_{t-1})) \) are independent of \( \theta_{t-1} \). Moreover, note that as \( \beta \) approaches 1, so that the time-inconsistency problem vanishes, \( \theta_p(\theta_{t-1}) \) approaches \( \bar{\theta} \), and thus the sequentially optimal rule provides full discretion to all types.

As in the two-type case, the sequentially optimal rule does not provide dynamic incentives. It therefore takes the form of a set of allowable savings rates, from which the government chooses the one that is closest to its flexible optimum. To understand why very high types are given no discretion, note that because of the bounded distribution of shocks, allowing flexibility for these types has no ex-ante welfare gain—such very high types would be overborrowing under any realized shock, so there is no tradeoff between commitment and flexibility for them. \( \theta_p(\theta_{t-1}) \) can be interpreted as the type above which the value of flexibility is exceeded by the value of commitment.

To understand why all types below the cutoff \( \theta_p(\theta_{t-1}) \) are given full discretion, consider the alternative of having a mechanism that admits “holes,” namely, where some interior interval of savings rates are not allowed. Given such a hole, the types whose flexible optimum is inside the hole would choose savings rates at the boundaries of the hole. Specifically, those inside the hole whose type is relatively high would reduce their savings by choosing the lower boundary—which is socially costly—and those inside the hole whose type is relatively low would increase their savings by choosing the upper boundary—which is socially beneficial. The resulting total change in welfare then depends on the slope of the density function; under Assumption 4, which effectively puts a lower bound on the elasticity of \( p(\theta_t|\theta_{t-1}) \) with respect to \( \theta_t \), the total welfare change of introducing a hole is always negative.

\section*{B.3 Ex-ante Optimal Rule}

We next consider the ex-ante optimal fiscal rule. For this analysis, we assume that the mechanism at time \( t \) admits savings rates that are piecewise continuously differentiable with respect to the history \( \theta^t \).\footnote{This assumption is without loss in our setting in the case of i.i.d. shocks, and it is made in other settings in related work such as Athey, Atkeson, and Kehoe (2005). We use this assumption in proving the second part of Proposition 9.} As in the two-type case, we begin by considering the i.i.d. benchmark.

**Proposition 8 (ex-ante optimum under continuum of i.i.d. shocks).** Suppose \( p(\theta_t|\theta_{t-1}) \) is independent of \( \theta_{t-1} \). Then the ex-ante optimum coincides with the sequential optimum.

**Proof.** See the Supplementary Appendix.

The intuition for this result is analogous to that of the two-type case. Under i.i.d. shocks, any ex-post suboptimality affects welfare on and off the equilibrium path equally, and hence cannot enhance efficiency. Consequently, dynamic incentives are not provided and the ex-ante optimum coincides with the sequential optimum. It of course follows that when shocks are i.i.d., the ex-ante optimum can be implemented with a renegotiated debt limit.

Consider now the case of persistent shocks, where \( p(\theta_t|\theta_{t-1}) \) depends on \( \theta_{t-1} \). We define persistence with the following condition.
Condition 1 (mechanism relevance of past information). There is a positive measure of types $\theta_{t-1}$ and $\theta_t$ such that $\theta_p(\theta_{t-1}) > \bar{\theta}$, $s^f(\theta_t) > s^f(\theta_p(\theta_{t-1}))$, and $s'(\theta_t) \neq 0$.

Condition 1 concerns the sequence of minimum savings policies implied by the sequential optimum described in Proposition 7. It states that in the sequentially optimal fiscal rule, there is a positive measure of types $\theta_{t-1}$ and $\theta_t$ with the property that, given $\theta_{t-1}$, the government of type $\theta_t$ at date $t$ has full discretion, so it spends above first-best level, and, moreover, such government has information which is locally relevant regarding the sequentially optimal mechanism at $t + 1$ (i.e., $s'(\theta_t) \neq 0$). The analog of Condition 1 is trivially satisfied in a two-type economy, as the low type always spends above best in the sequential optimum, and this type also has information about the future sequentially optimal mechanism. In the setting with a continuum of types, Condition 1 is always satisfied if $s'(\theta_t) \neq 0$ for some positive measure of types $\theta_t$, so that current information is relevant to future mechanisms, and if $\beta$ is sufficiently close to 1, so that such types $\theta_t$ with mechanism-relevant information have full discretion at $t$ starting from some $\theta_{t-1}$.

While an explicit characterization of the ex-ante optimal rule becomes more complicated under a continuum of persistent shocks, we show that under Condition 1, this rule does not coincide with the sequentially optimal rule, and it exhibits history dependence.

Proposition 9 (ex-ante optimum under continuum of persistent shocks). Suppose Condition 1 is satisfied. The ex-ante optimum has the following features:

(i) It does not coincide with the sequential optimum, and

(ii) It exhibits history dependence: there exist $\theta^t$ and $\theta^k$ with $\theta_t = \theta_k$ and $\theta_{t-1} = \theta_{k-1}$ for which $s_t(\theta^t) \neq s_k(\theta^k)$.

Proof. See the Supplementary Appendix. \qed

The intuition for Proposition 9 is familiar from the two-type economy. For the first part of the proposition, suppose by contradiction that the ex-ante optimum coincided with the sequential optimum. We show that ex-ante welfare can then be improved with a perturbation that induces ex-post suboptimality. For concreteness, suppose that $\theta_p(\theta_{t-1}) > \bar{\theta}$ for all $\theta_{t-1}$ and $\theta'_p(\theta_{t-1}) > 0$, so the sequentially optimal rule at date 0 becomes more relaxed the higher is the shock $\theta_{t-1}$. Consider perturbing the mechanism by assigning at date 1 the fiscal rule associated with a cutoff $\theta_p(\theta_0 + \mu(\theta_0))$, for some $\mu(\theta_0) > 0$ arbitrarily small. This relaxes incentive compatibility constraints at date 0, allowing to increase the savings rates assigned to all types $\theta_0 < \theta_p(\theta_{t-1})$, from $s^f(\theta_0)$ to $s^f(\theta_0) + \varepsilon(\theta_0)$, for some $\varepsilon(\theta_0) > 0$ that satisfies incentive compatibility. By envelope arguments analogous to those of Section 4, we can show that ex-ante welfare increases as a result: the first-order gain of bringing savings closer to first best at date 0 outweighs the second-order loss of assigning suboptimal rules at date 1. Therefore, as in the two-type case, the ex-ante optimal mechanism uses a threat of lack of fiscal discipline in the future to induce discipline today.

The logic for the second part of Proposition 9 is also analogous to that used for the two-type economy. History dependence arises because the mechanism provides dynamic incentives. That is, because the shock at date $t - 2$ predicts the realization of the shock at $t - 1$, the shock at $t - 2$ affects the relative tightness of incentive compatibility constraints at $t - 1$, and therefore it affects the policies that are chosen at $t$ to provide dynamic incentives to the government at $t - 1$. 

35
C Proofs for Subsection 5.1

C.1 Proofs of Proposition 1 and Corollary 1

Consider the problem defined by (16)–(17). We first show that Assumption 2 implies that the solution to this problem admits pooling. We use the definition of the first-best benchmark given in (8) and we define the full flexibility benchmark as a sequence of savings rates satisfying

\[ s^f_t = s^f(\theta^t) \text{ if } \theta_t = \theta^t, \]

where for \( \theta^t \in \{ \theta^L, \theta^H \} \),

\[ \theta^i U'(1 - s^f(\theta^i)) = \beta \tilde{\theta}^i U'(s^f(\theta^i)). \]  

(C.1)

Assumption 2 together with the concavity of \( U(\cdot) \) imply

\[ s^f(\theta^H) < s^f(\theta^L) < s^{fb}(\theta^H) < s^{fb}(\theta^L). \]  

(C.2)

Hence, (17) must bind for some type in the solution to (16)–(17); otherwise, the solution would satisfy (8), but given (C.2) and the strict concavity of \( U(\cdot) \), (17) would then be violated.

Note furthermore that the solution must admit \( s^t(\theta^H) \leq s^t(\theta^L) \). This follows since pooling both types to the same savings rate must weakly lower welfare. Specifically, a perturbation which assigns the low type’s savings rate to the high type must weakly lower welfare:

\[ \theta^H \tilde{\theta}^H \left( U(1 - s^t(\theta^H)) - U(1 - s^t(\theta^L)) \right) + \left( U(s^t(\theta^H)) - U(s^t(\theta^L)) \right) \geq 0. \]  

(C.3)

Analogously, a perturbation which assigns the high type’s savings rate to the low type must weakly lower welfare:

\[ \theta^L \tilde{\theta}^L \left( U(1 - s^t(\theta^L)) - U(1 - s^t(\theta^H)) \right) + \left( U(s^t(\theta^L)) - U(s^t(\theta^H)) \right) \geq 0. \]  

(C.4)

Adding (C.3) and (C.4) gives

\[ \left( \frac{\theta^H}{\tilde{\theta}^H} - \frac{\theta^L}{\tilde{\theta}^L} \right) \left( U(1 - s^t(\theta^H)) - U(1 - s^t(\theta^L)) \right) \geq 0, \]

which requires that \( s^t(\theta^H) \leq s^t(\theta^L) \).

Finally, note that it must be that (17) is an equality for \( \theta_t = \theta^L \). Suppose instead that it were a strict inequality. Then given the above argument, (17) must be an equality for \( \theta_t = \theta^H \). Substitution of (17) into the left hand side of (C.3) then implies

\[ (1 - \beta) \left[ U(s^t(\theta^H)) - U(s^t(\theta^L)) \right] \geq 0, \]  

(C.5)

which implies \( s^t(\theta^H) \geq s^t(\theta^L) \). Given that \( s^t(\theta^H) \leq s^t(\theta^L) \), this means that \( s^t(\theta^H) = s^t(\theta^L) \), and thus (17) is an equality for \( \theta_t = \theta^L \).

To establish that there is pooling, suppose that there is separation so that (17) is ignored for the high type, and consider the first order conditions to (16)–(17). Let \( \phi \) correspond to
the Lagrange multiplier on (17) for the low type. First order conditions yield:

\[
\begin{align*}
1 + \frac{\phi}{p(\theta^L|\theta_{t-1})} & = \frac{\tilde{\theta}^L U''(s_t(\theta^L))}{\tilde{\theta}^L U'(1 - s_t(\theta^L))}, & \text{(C.6)} \\
1 + \beta \frac{\phi}{p(\theta^L|\theta_{t-1})} & = \frac{\tilde{\theta}^L U''(s_t(\theta^L))}{\tilde{\theta}^L U'(1 - s_t(\theta^L))}, & \text{(C.7)}
\end{align*}
\]

Equation (C.6) implies \( s_t(\theta^L) < s_f^b(\theta^L) \). Moreover, note that Assumption 2 implies

\[
\frac{\theta^L}{\tilde{\theta}^L} > \beta \frac{\theta^H}{\tilde{\theta}^H},
\]

and thus (C.7) implies \( s_t(\theta^H) > s_f^b(\theta^H) \). Therefore, from (C.2), this means that \( s_f^L(\theta^L) < s_t(\theta^H) < s_t(\theta^L) \), but this violates (17) since the low type can make itself strictly better off by claiming to be a high type. Therefore, (17) must hold with equality for both types and the mechanism features pooling.

Since the equilibrium features pooling, it follows that the optimal pooling level necessarily satisfies first order condition (21) where the pooling level depends only on \( \theta_{t-1} \). Since the solution to (21) admits a savings rate between \( s_f^b(\theta^H) \) and \( s_f^b(\theta^L) \), and since this savings rate is then above both \( s_f^H(\theta^H) \) and \( s_f^L(\theta^L) \), it follows that the equilibrium can be implemented with a required minimum savings rate that solves (21), which both types would choose. From (1), it is clear that requiring such a minimum savings rate is equivalent to imposing a maximum debt limit, which proves the corollary.

\[\blacksquare\]

**D Proofs for Subsection 5.2**

**D.1 Proof of Lemma 1**

In order to prove this result, we begin by considering a relaxed program which effectively lets (1) be a weak inequality so as to allow for money burning:
\[
Q(\theta^i, Z) = \max_{\{u^L, y^L, u^H, y^H, Z^L, Z^H\}} \left\{ p(\theta^L|\theta^i)(\theta^L u^L + \tilde{\theta}^L y^L + \delta Q(\theta^L, Z^L)) + p(\theta^H|\theta^i)(\theta^H u^H + \tilde{\theta}^H y^H + \delta Q(\theta^H, Z^H)) \right\} \\
\text{s.t.} \\
U^{-1}(u^L) + U^{-1}(y^L) \leq 1, \\
U^{-1}(u^H) + U^{-1}(y^H) \leq 1,
\]

(D.1)–(D.7) is identical to (23)–(27) if (D.2) and (D.3) hold with equality, in which case \(w^i = U(1 - s^i)\) and \(y^i = U(s^i)\). We will eventually establish that in the solution, (D.2) and (D.3) hold with equality, and thus (D.1)–(D.7) is identical to (23)–(27). Note that, in this program, \(Z^i\) and \(\overline{Z}^i\) are respectively the lowest and highest values of \(Z\) given \(\theta^i\) for which a solution to the program exists. We establish some preliminary lemmas regarding the solution to the relaxed program.

**Lemma 5.** \(Q(\theta^i, Z)\) is weakly concave in \(Z \in [Z^i, \overline{Z}^i]\).

**Proof.** Consider the sequence problem defined by (D.1)–(D.7), and let

\[
\gamma^*(\theta^i, Z) = \left\{ \{u(\theta^i), y(\theta^i)\} \_\theta^i \right\}_{t=0}^{\infty}
\]
correspond to the stochastic sequence of \(u\)’s and \(y\)’s defined by forward iteration which solves (D.1)–(D.7) for some given \(\theta_{-1} = \theta^i\) and \(Z_0 = Z\). Suppose that \(Z' \in [Z^i, \overline{Z}^i]\) and \(Z'' \in [Z^i, \overline{Z}^i]\) with \(Z'' > Z'\), and consider the solution to the sequence problem for \(Z = \kappa Z' + (1 - \kappa) Z'' \equiv Z^\kappa\). Define a potential solution

\[
\gamma^\kappa = \kappa \gamma^*(\theta^i, Z') + (1 - \kappa) \gamma^*(\theta^i, Z'').
\]

\(\gamma^\kappa\) is a convex combination of the stochastic \(u\) and \(y\) sequences under \(Z'\) and \(Z''\). Because the set of \(u\) and \(y\) sequences that satisfy the sequence analogue of the constraint set in (D.2)–(D.7) is convex, it follows that \(\gamma^\kappa\) satisfies the constraints of the problem for \(Z = Z^\kappa\). Therefore, the value of \(Q(\theta^i, Z^\kappa)\) must be weakly greater than the welfare under \(\gamma^\kappa\); that is:

\[
Q(\theta^i, Z^\kappa) \geq \kappa Q(\theta^i, Z') + (1 - \kappa)Q(\theta^i, Z''). \\
\]

(D.8)

It follows from (D.8) that \(Q(\theta^i, Z)\) is weakly concave. \(\square\)

Define \(Z^i_{\text{max}} = \arg\max_{Z \in [Z^i, \overline{Z}^i]} Q(\theta^i, Z)\). We now use Lemma 5 to characterize \(Z^i_{\text{max}}\) and \(Q(\theta^i, Z^i_{\text{max}})\).

38
Lemma 6. The solution to (D.1)–(D.7) for \( Z = Z_{\text{max}}^i \) has the following properties:

(i) (D.5) holds with equality and (D.6) holds as a strict inequality,

(ii) (D.2) and (D.3) both hold with equality.

Proof. Proof of part (i). We establish this result in three steps. We take into account that the solution to (D.1)–(D.7) for \( Z = Z_{\text{max}}^i \) is equivalent to the solution to (D.1)–(D.7) ignoring (D.4).

Step 1. Either (D.5) or (D.6) hold with equality. Suppose by contradiction that this is not the case. Then (D.5) and (D.6) can be ignored, and the solution admits the first-best allocation defined by (8) and \( Z = Z_{\text{max}}^i \) for \( i = \{L, H\} \), as this maximizes welfare. This implies that the infinite repetition of the first best allocation is incentive compatible, which means that in fact \( Q(\theta^i, Z^i) = Z^i \) for \( i = \{L, H\} \). But the same arguments as in the proof of Proposition 1 then imply that (D.5) is violated, leading to a contradiction.

Step 2. Suppose that in the solution, (D.6) holds with equality. Then there is bunching, with \( u^L = u^H \) and \( y^H = y^L \), and (D.2) and (D.3) both hold with equality. To see why, note first that the solution admits \( u^H \geq u^L \) and \( y^L \geq y^H \). This follows from the fact that a perturbation that changes the high type’s allocation to the low type’s (so that there is bunching) and sets \( Z = Z_{\text{max}}^i \) for \( i = \{L, H\} \) must weakly lower welfare:

\[
\theta^H(u^H - u^L) + \tilde{\theta}^H(y^H - y^L) \geq 0. \tag{D.9}
\]

It can be verified that this perturbation satisfies (D.2)–(D.3) and (D.5)–(D.7). Analogously, a perturbation that changes the low type’s allocation to the high type’s must weakly lower welfare:

\[
\theta^L(u^L - u^H) + \tilde{\theta}^L(y^L - y^H) \geq 0. \tag{D.10}
\]

Adding (D.9) and (D.10) gives

\[
\left( \frac{\theta^H}{\theta^L} - \frac{\theta^L}{\theta^H} \right) (u^H - u^L) \geq 0 \text{ and } \left( \frac{\tilde{\theta}^L}{\tilde{\theta}^H} - \frac{\tilde{\theta}^H}{\tilde{\theta}^L} \right) (y^L - y^H) \geq 0,
\]

which requires \( u^H \geq u^L \) and \( y^L \geq y^H \).

Next, note that a perturbation that changes the high type’s allocation and continuation allocation to be the same as the low type’s must also weakly lower welfare:

\[
\theta^H(u^H - u^L) + \tilde{\theta}^H(y^H - y^L) + \delta(Q(\theta^H, Z^H) - Z^L) \geq 0.
\]

Substitution of (D.6) holding with equality into the above condition gives

\[
\left( 1 - \frac{1}{\beta} \right) \theta^H(u^H - u^L) \geq 0,
\]

which means that \( u^H \leq u^L \). Combined with the result above, this implies \( u^H = u^L \).

Finally, note that conditional on \( u^H = u^L \), setting \( y^H = y^L \), so that (D.2) and (D.3) hold with equality and \( Z^i = Z_{\text{max}}^i \) for \( i = \{L, H\} \), yields the highest feasible welfare. Moreover,
such a solution satisfies (D.5) and (D.6), so it is incentive compatible. Therefore, there is bunching and the resource constraints hold with equality.

**Step 3.** A solution where (D.6) holds with equality is suboptimal. From Step 2, such a solution admits bunching, implying that $Q(\theta^H, Z_{\text{max}}^i) = Z_{\text{max}}^L$. By construction, it must also be that $Q(\theta^L, Z_{\text{max}}^i) = Z_{\text{max}}^H$. Thus, the solution admits the same repeated level of bunching which is independent of the previous period’s shock. However, this level of bunching yields a welfare strictly below that achieved in the sequential optimum described in Proposition 1, where the level of bunching depends on the previous period’s shock. Therefore, (D.6) holds as a strict inequality in the solution, and by Step 1, (D.5) holds with equality.

**Proof of part (ii).** By the previous steps, the solution is such that (D.5) holds as an equality and (D.6) as an inequality. We now show that (D.2) and (D.3) hold with equality. Suppose first that (D.2) is a strict inequality. Consider a perturbation that decreases $u^L$ and increases $y^L$ while holding $\theta^L u^L + \beta \tilde{\theta}^L y^L$ constant. This perturbation clearly increases welfare. Moreover, this perturbation leaves (D.5) unaffected, and for a small enough perturbation, (D.6) continues to hold. Therefore, this perturbation is incentive compatible and strictly increases welfare. Suppose next that (D.3) is an inequality. Consider a perturbation that decreases $u^H$ and increases $y^H$ while holding $\theta^H u^H + \beta \tilde{\theta}^H y^H$ constant. It follows from Assumption 2, which implies (C.8), that this perturbation increases welfare. Moreover, this perturbation leaves (D.5) unaffected, and for a small enough perturbation, (D.6) continues to hold. Therefore, this perturbation is incentive compatible and strictly increases welfare.

Finally, we show that in the solution, $u^L < u^H$ and $y^L > y^H$. From Step 2 in the proof of part (i), $u^L \leq u^H$ and $y^L \geq y^H$. Since (D.2) and (D.3) hold with equality, if it is the case that $u^L = u^H$, then it must be that $y^L = y^H$, and vice versa, so that there would be bunching. However, by Step 3 of the proof of part (i), a solution that admits bunching is suboptimal. It thus follows that $u^L < u^H$ and $y^L > y^H$.

We now use the fact that $Z_{\text{max}}^i$ characterizes the global optimum of $Q(\theta^i, Z)$ to characterize $Q(\theta^i, Z)$.

**Lemma 7.** $Q(\theta^i, Z)$ has the following properties.

(i) $\exists Z_{\text{min}}^i \in [Z^i, Z_{\text{max}}^i]$ s.t. $Q(\theta^i, Z)$ is continuously differentiable in $Z$ if $Z \in (Z_{\text{min}}^i, Z_{\text{max}}^i]$.

(ii) If $Z \in (Z_{\text{min}}^i, Z_{\text{max}}^i)$, $Q(\theta^i, Z)$ is strictly concave in $Z$.

**Proof.** We establish these results in four steps.

**Step 1.** We first establish that $Q(\theta^i, Z)$ is continuously differentiable in $Z$ at $Z = Z_{\text{max}}^i$ with a derivative equal to zero. Consider the solution to (D.1)–(D.7) for $Z = Z_{\text{max}}^i$. Let $s^L$ and $s^H$ correspond to the associated savings rates in the solution, where by the proof of part (ii) of Lemma 6, $s^H < s^L$. Define $s^L_{\varepsilon} = s^L + \varepsilon$ and $s^H_{\varepsilon}$ as the solution to

$$
\theta^L(U(1-s^L_{\varepsilon}) - U(1-s^H_{\varepsilon})) + \beta \tilde{\theta}^L(U(s^L_{\varepsilon}) - U(s^H_{\varepsilon}))
= \theta^L(U(1-s_{\varepsilon}^L) - U(1-s_{\varepsilon}^H)) + \beta \tilde{\theta}^L(U(s_{\varepsilon}^L) - U(s_{\varepsilon}^H)).
$$

(D.11)
Let
\[
Z_\varepsilon = Z^i_{\max} + \left\{ p(\theta^L|\theta^{-i})(\theta^L(U(1-s^L_\varepsilon) - U(1-s^L)) + \tilde{\theta}^L(U(s^L_\varepsilon) - U(s^L))) + p(\theta^H|\theta^{-i})(\theta^H(U(1-s^H_\varepsilon) - U(1-s^H)) + \tilde{\theta}^H(U(s^H_\varepsilon) - U(s^H))) \right\}
\]  
(D.12)
and
\[
Q_\varepsilon = Q(\theta^i, Z^i_{\max}) + \left\{ p(\theta^L|\theta^{-i})(\theta^L(U(1-s^L_\varepsilon) - U(1-s^L)) + \tilde{\theta}^L(U(s^L_\varepsilon) - U(s^L))) + p(\theta^H|\theta^{-i})(\theta^H(U(1-s^H_\varepsilon) - U(1-s^H)) + \tilde{\theta}^H(U(s^H_\varepsilon) - U(s^H))) \right\}.
\]  
(D.13)

From the definition of \(Z^i_{\max}\), it must be that the derivative of \(Q_\varepsilon\) with respect to \(\varepsilon\) at \(\varepsilon = 0\) is zero, as the objective attains a local maximum, where we have taken into account that the perturbation continues to satisfy (D.2)–(D.3) and (D.5)–(D.7). Note that it cannot be that \(\theta^L|\theta^{-i} \neq \theta^L|\theta^i\) and \(\theta^H|\theta^{-i} \neq \theta^H|\theta^i\), this could be true if \(s^L\) and \(s^H\) are chosen at the first-best level, but this is also ruled out in Step 1 in the proof of part (i) of Lemma 6. Therefore, it cannot also be that \(Z_\varepsilon\) is at its local maximum. It thus follows that one can use this perturbation to apply Lemma 1 of Benveniste and Scheinkman (1979) to show that \(Q(\theta^i, Z)\) is continuously differentiable in \(Z\) at \(Z = Z^i_{\max}\) and has a derivative of zero.

**Step 2.** Define \(Z^i_{\min}\) as follows. If
\[
\lim_{\varepsilon > 0, \varepsilon \to 0} \frac{Q(\theta^i, Z^i + \varepsilon) - Q(\theta^i, Z^i)}{\varepsilon} < \frac{1 - p(\theta^i|\theta^i)}{p(\theta^i|\theta^i)},
\]
then \(Z^i_{\min} = Z^i\). Otherwise, \(Z^i_{\min}\) is the highest point in \([Z^i, Z^i]\) such that
\[
\lim_{\varepsilon > 0, \varepsilon \to 0} \frac{Q(\theta^i, Z^i_{\min} + \varepsilon) - Q(\theta^i, Z^i_{\min})}{\varepsilon} \leq \frac{1 - p(\theta^i|\theta^i)}{p(\theta^i|\theta^i)} \leq \lim_{\varepsilon > 0, \varepsilon \to 0} \frac{Q(\theta^i, Z^i_{\min}) - Q(\theta^i, Z^i_{\min} - \varepsilon)}{\varepsilon},
\]
where such a point necessarily exists given Step 1 and the concavity of \(Q(\cdot)\). Note further that (D.1)–(D.7) can be represented by
\[
\max_{\{u^L,y^L,u^H,y^H,Z^L,Z^H\}} \left\{ \frac{(p(\theta^L|\theta^i) + \lambda p(\theta^L|\theta^{-i})) (\theta^L u^L + \tilde{\theta}^L y^L + \delta Q(\theta^L, Z^L))}{p(\theta^H|\theta^i) + \lambda p(\theta^H|\theta^{-i})) (\theta^H u^H + \tilde{\theta}^H y^H + \delta Q(\theta^H, Z^H))} \right\}
\]  
(D.15)
s.t. (D.2)–(D.3) and (D.5)–(D.7).

(D.15) corresponds (D.1)–(D.7) where \(\lambda\) is the Lagrange multiplier on the threat-keeping constraint (D.4). By the envelope condition,
\[
\lim_{\varepsilon > 0, \varepsilon \to 0} \frac{Q(\theta^i, Z + \varepsilon) - Q(\theta^i, Z)}{\varepsilon} \leq \lambda \leq \lim_{\varepsilon > 0, \varepsilon \to 0} \frac{Q(\theta^i, Z) - Q(\theta^i, Z - \varepsilon)}{\varepsilon}.
\]

It thus follows from concavity and the definition of \(Z^i_{\min}\) above that if \(Z \in (Z^i_{\min}, Z^i_{\max})\), then
\[
p(\theta^L|\theta^i) + \lambda p(\theta^L|\theta^{-i}) > 0 \text{ and } p(\theta^H|\theta^i) + \lambda p(\theta^H|\theta^{-i}) > 0,
\]  
(D.16)
so that the objective in (D.15) puts positive weight on the realization of both states.

**Step 3.** Analogous arguments to those used in the proof of Lemma 6 imply that given (D.16), the solution to (D.15) has the following properties: (D.5) holds with equality and (D.6) as a strict inequality; (D.2) and (D.3) hold with equality; the solution admits \( s^L > s^H \). Given these observations, a perturbation as the one used in Step 1 can be used here, and the same arguments from Step 1 imply that \( Q(\theta^i, Z) \) is continuously differentiable in \( Z \).

**Step 4.** We now show that \( Q(\theta^i, Z) \) is strictly concave in this range. Consider the argument of concavity in the proof of Lemma 5. The potential solution yields welfare\( \kappa Q(\theta^i, Z^*) + (1 - \kappa)Q(\theta^i, Z'') \), while leaving the resource constraints (D.2) and (D.3) as strict inequalities in the initial date. Given the arguments in Step 3, welfare can be strictly increased by letting (D.2) and (D.3) hold as equalities, implying that (D.8) must be a strict inequality. Thus, \( Q(\theta^i, Z) \) is strictly concave.

We now characterize the solution to the program for \( Z \in (Z^i_{\min}, Z^i_{\max}) \), where we denote by \( Z^L(\theta^i, Z) \) and \( Z^H(\theta^i, Z) \) the optimal values of \( Z^L \) and \( Z^H \) respectively given \( \theta^i \) and \( Z \).

**Lemma 8.** If \( Z \in (Z^i_{\min}, Z^i_{\max}) \), the solution to (D.1)–(D.7) has the following properties:

(i) (D.2) and (D.3) hold with equality,

(ii) \( Z^L(\theta^i, Z) = Z^L_{\max} \) for \( \theta^i \in \{\theta^L, \theta^H\} \),

(iii) \( Z^H(\theta^i, Z) < Z^H_{\max} \) for \( \theta^i \in \{\theta^L, \theta^H\} \),

(iv) \( Z^H(\theta^H, Z) \) is strictly decreasing in \( Z \), and

(v) \( Z^H(\theta^H, Z^H_{\max}) > Z^H(\theta^L, Z^L_{\max}) > Z^H_{\min} \).

**Proof.** Proof of part (i). This follows from Step 3 in the proof of Lemma 7.

**Proof of part (ii).** Consider the problem as represented in (D.15). Suppose it were the case that \( Z^L(\theta^i, Z) < Z^L_{\max} \). Then a perturbation which moves \( Z^L \) in the direction of \( Z^L_{\max} \) strictly increases welfare by increasing \( Q(\theta^L, Z^L) \). Furthermore, it relaxes (D.5) and, since (D.6) is a strict inequality in the solution to the program (from Step 3 in the proof of Lemma 7), (D.6) continues to hold.

**Proof of part (iii).** Consider the solution to (D.15) given that (D.2) and (D.3) hold with equality. Let \( s^L \) and \( s^H \) correspond to the savings rates in the low and high shocks, respectively. Let \( \phi \) be the Lagrange multiplier on (D.5). First order conditions with respect to \( s^L \) and \( s^H \) yield

\[
\frac{U'(1 - s^L)}{U'(s^L)} = \left( \frac{\tilde{\theta}^L 1 + \beta p(\theta^L|\theta^i) + \lambda p(\theta^L|\theta^{-i})}{\theta^L 1 + \beta p(\theta^L|\theta^i) + \lambda p(\theta^L|\theta^{-i})} \right),
\]

\[
\frac{U'(1 - s^H)}{U'(s^H)} = \left( \frac{\tilde{\theta}^H 1 + \beta p(\theta^H|\theta^i) + \lambda p(\theta^H|\theta^{-i})}{\theta^H 1 + \beta p(\theta^H|\theta^i) + \lambda p(\theta^H|\theta^{-i})} \right).
\]

\[\text{(D.17)}\]

\[\text{(D.18)}\]

42
Note that $\phi > 0$; otherwise, the same arguments as those used in Step 1 in the proof of part (i) of Lemma 6 would imply that the repeated first-best allocation is incentive compatible, leading to a contradiction. Finally, first order conditions with respect to $Z^H$ yield

$$
\lim_{\varepsilon \to 0, \varepsilon > 0} \frac{Q(\theta^H, Z^H) - Q(\theta^H, Z^H - \varepsilon)}{\varepsilon} \geq \frac{\phi}{p(\theta^H|\theta^i) + \lambda p(\theta^H|\theta^{-i})},
$$

\begin{equation}
\geq \lim_{\varepsilon \to 0, \varepsilon > 0} \frac{Q(\theta^H, Z^H + \varepsilon) - Q(\theta^H, Z^H)}{\varepsilon},
\end{equation}

where we have taken into account that $Z^H$ may be below $Z^H_{\text{min}}$, in which case $Q(\theta^H, Z^H)$ may not necessarily be differentiable. Given the definition of $Z^H_{\text{max}}$, and the fact that $Q_Z(\theta^H, Z^H_{\text{max}}) = 0$, it follows from (D.19) that $Z^H(\theta^i, Z) < Z^H_{\text{max}}$, since $\phi > 0$.

**Proof of part (iv).** Suppose that $\theta^i = \theta^H$ and consider $Z' \in (Z^H_{\text{min}}, Z^H_{\text{max}}]$ and $Z'' \in (Z^H_{\text{min}}, Z^H_{\text{max}}] \setminus [Z^H_{\text{min}}, Z^H_{\text{max}}]$ with $Z'' > Z'$. Given part (ii) of Lemma 7, it follows that $Z''$ is associated with multiplier $\lambda''$ in (D.15) and $Z''$ is associated with multiplier $\lambda'$ in (D.15) where $\lambda' < \lambda'' < 0$. We will establish that $Z^H(\theta^H, Z'') < Z^H(\theta^H, Z')$. Suppose instead that $Z^H(\theta^H, Z'') \geq Z^H(\theta^H, Z')$. Let $\phi'$ and $\phi''$ correspond to the Lagrange multipliers on (D.5) for the program for $Z = Z''$ and $Z = Z'$, respectively. From (D.19) together with the concavity of $Q(\cdot)$, it must be that

$$
\frac{\phi'}{p(\theta^H|\theta^i) + \lambda' p(\theta^H|\theta^L)} \geq \frac{\phi''}{p(\theta^H|\theta^i) + \lambda'' p(\theta^H|\theta^L)}.
$$

Substituting into (D.18), taking into account (C.8), this implies that the solution $s^{H*}(\cdot)$ must satisfy

$$
\begin{equation}
\begin{aligned}
\frac{\phi'}{p(\theta^H|\theta^i) + \lambda' p(\theta^H|\theta^L)} &\geq \frac{\phi''}{p(\theta^H|\theta^i) + \lambda'' p(\theta^H|\theta^L)}.
\end{aligned}
\end{equation}
$$

Substituting into (D.17) implies that the solution $s^{L*}(\cdot)$ must satisfy

$$
\begin{equation}
\begin{aligned}
\frac{s^{L*}(\theta^H, Z')} {s^{L*}(\theta^H, Z'')} &< \frac{s^{L*}(\theta^H, Z')} {s^{L*}(\theta^H, Z')},
\end{aligned}
\end{equation}
$$

where $s^{L*}(\theta^H, Z')$ is defined in (8). From Step 3 of the proof of Lemma 7,

$$
\begin{equation}
\begin{aligned}
s^{H*}(\theta^H, Z') &< s^{L*}(\theta^H, Z').
\end{aligned}
\end{equation}
$$

Note that $\theta^L U(1 - s) + \beta \theta^L U(s)$ is strictly decreasing in $s$ for $s \geq s^{L*}(\theta^H) > s^{I}(\theta^L)$, where we have appealed to (C.2). Therefore, conditions (D.21), (D.23), and (D.24) combined together imply that

$$
\begin{equation}
\begin{aligned}
\theta^L(U(1 - s^{L*}(\theta^H, Z'')) - U(1 - s^{H*}(\theta^H, Z''))) + \beta \theta^L(U(s^{L*}(\theta^H, Z'')) - U(s^{H*}(\theta^H, Z''))) \\
< \theta^L(U(1 - s^{L*}(\theta^H, Z')) - U(1 - s^{H*}(\theta^H, Z'))) + \beta \theta^L(U(s^{L*}(\theta^H, Z')) - U(s^{H*}(\theta^H, Z'))).
\end{aligned}
\end{equation}
$$
Given that (D.5) holds with equality and \(Z^L(\theta^i, Z) = Z^L_{\text{max}}\) from part (ii), this implies
\[
\beta \delta (Z^H(\theta^H, Z^H) - Q(\theta^L, Z^L_{\text{max}})) < \beta \delta (Z^H(\theta^H, Z') - Q(\theta^L, Z^L_{\text{max}})),
\]
which contradicts the fact that \(Z^H(\theta^H, Z^H) \geq Z^H(\theta^H, Z')\).

**Proof of part (v).** First note that \(Z^H(\theta^H, Z^H_{\text{max}}) > Z^H(\theta^L, Z^L_{\text{max}})\) follows from analogous arguments to those used in the proof of part (iv), taking into account that the associated value of \(\lambda\) is 0 for \(Z = Z^i_{\text{max}}, i = \{L, H\}\). We are then left to show that \(Z^H(\theta^L, Z^L_{\text{max}}) > Z^H_{\text{min}}\).

Suppose instead that \(Z^H(\theta^L, Z^L_{\text{max}}) \leq Z^H_{\text{min}}\). By the definition of \(Z^H_{\text{min}}\) in Lemma 7, using (D.19) and the fact that \(\lambda = 0\) for \(Z = Z^i_{\text{max}}\), it follows that
\[
\phi \geq \frac{1}{\beta} \frac{(1 - p(\theta^i|\theta^i))^2}{p(\theta^i|\theta^i)}. \tag{D.25}
\]
Note that by the arguments in the proof of part (iv), \(s^{H*}(\theta^L, Z^L_{\text{max}}) < s^{fb}(\theta^L)\). From (D.18), taking into account that \(\lambda = 0\), this means that
\[
\frac{\theta^H}{\theta^L} - \frac{\tilde{\theta}^H}{\tilde{\theta}^L} > \phi \frac{(1 - \beta)}{1 - p(\theta^i|\theta^i)}. \tag{D.26}
\]
Combining (D.25) with (D.26) implies that
\[
\frac{\theta^H}{\theta^L} - \frac{\tilde{\theta}^H}{\tilde{\theta}^L} > \frac{1 - p(\theta^i|\theta^i)}{p(\theta^i|\theta^i)} \left( \frac{1}{\beta} - 1 \right). \tag{D.27}
\]
But this contradicts Assumption 2, completing the proof.

By Lemma 8, the relaxed program in (D.1)–(D.7) is equivalent to the original program in (23)–(27) if we define \(V^i = Z^i_{\text{min}}\) and \(\overline{V}^i = Z^i_{\text{max}}\). This is because (D.2) and (D.3) both hold with equality, and for \(Z \in (Z^i_{\text{min}}, Z^i_{\text{max}}]\), \(Z^L(\theta^i, Z) = (Z^L_{\text{min}}, Z^L_{\text{max}})\) and \(Z^H(\theta^i, Z) \in (Z^H_{\text{min}}, Z^H_{\text{max}}]\), so that \(V^i\) and \(\overline{V}^i\) effectively correspond to the minimum and maximum values of \(V\) that would ever be reached given that the equilibrium begins with the ex-ante optimum with \(Z_0 = Z^i_{\text{max}}\). It follows then from Lemma 7 that \(W(\theta^i, V)\) is strictly increasing in \(V\), strictly concave, and continuously differentiable in \(V\) over the range \((V^i, \overline{V}^i)\). \(\blacksquare\)

## D.2 Proof of Proposition 2

If shocks are i.i.d., \(p(\theta^L|\theta^i) = p(\theta^H|\theta^i) = 0.5\) and \(W(\theta^i, V) = V\). Moreover, \(\overline{V}^L = \overline{V}^H = \overline{V}\) and \(\overline{V}^L = \overline{V}^H = \overline{V}\) since the value and solution to (23)–(27) is independent of \(\theta^i\). Now consider the program starting from \(V = \overline{V}\), which is the solution to the ex-ante optimum. Let us denote the solution as in (29).

Analogous arguments to those used in the proof of Lemma 6 imply that in the solution, either (25) and (26) both hold as equalities with \(s^{L*}(\theta^i, \overline{V}) = s^{H*}(\theta^i, \overline{V})\), so that there is bunching, or alternatively (25) holds as an equality and (26) as a strict inequality. We consider the latter case first and rule it out. Note that the same arguments as those used in the proof
of Proposition 1 imply that if there is separation, the solution admits

$$s^{fb}(\theta^H) < s^{H*}(\theta^i, \bar{V}) < s^{L*}(\theta^i, \bar{V}) < s^{fb}(\theta^L).$$

(D.28)

This means that if the solution admits \( V^{L*}(\theta^i, \bar{V}) = V^{H*}(\theta^i, \bar{V}) = \bar{V} \), then from (C.2), (25) would be violated. Therefore, for (25) to hold as an equality and (26) as a strict inequality, it is necessary that \( V^{L*}(\theta^i, \bar{V}) < \bar{V} \) or \( V^{H*}(\theta^i, \bar{V}) < \bar{V} \). It is clear that setting \( V^{L*}(\theta^i, \bar{V}) = \bar{V} \) maximizes social welfare while fully relaxing (25), so the only possibility to consider is \( V^{H*}(\theta^i, \bar{V}) < \bar{V} \). Consider an increase in \( V^H \) and an increase in \( s^H \) that leaves the following term unchanged:

$$\theta^L U(1 - s^H) + \beta \tilde{\theta} U(s^H) + \beta \delta V^H.$$ 

Such a perturbation leaves (25) unchanged, and since (26) was satisfied with strict inequality, (D.28), the change in welfare from an arbitrarily small perturbation. One can show that given (C.8) and (D.28), the change in welfare from an arbitrarily small perturbation takes the same sign as \( \theta^L / \beta - \theta^H \) which is positive, so that the perturbation strictly increases welfare.

This implies that the equilibrium admits bunching with \( s^{L*}(\theta^i, \bar{V}) = s^{H*}(\theta^i, \bar{V}) \). Conditional on bunching, the optimal mechanism assigns \( V^{L*}(\theta^i, \bar{V}) = \bar{V} \) and \( V^{H*}(\theta^i, \bar{V}) = \bar{V} \) since (25) and (26) are trivially satisfied without the use of dynamic incentives. Therefore, the ex-ante optimum corresponds to the sequential optimum and Proposition 1 applies.

### D.3 Proof of Lemma 2

Parts (i) and (ii) follow directly from Lemma 8 in the solution to the relaxed problem. We are left then to prove part (iii). Let \( \phi \) correspond to the Lagrange multiplier on (25). First order conditions with respect to \( s^L \), \( s^H \), and \( V^H \), respectively, yield

\[
\frac{U'(1 - s^L)}{U'(s^L)} = \frac{\phi}{\left( \frac{\hat{\theta}^L 1 + \beta p(\theta^L|\theta^i) + \lambda p(\hat{\theta}^L|\theta^i)}{\hat{\theta}^L 1 + p(\theta^L|\theta^i) + \lambda p(\theta^L|\theta^i)} \right)}, \\
\frac{U'(1 - s^H)}{U'(s^H)} = \frac{\phi}{\left( \frac{\hat{\theta}^H - \hat{\theta}^L}{\hat{\theta}^H - \hat{\theta}^L} \frac{p(\theta^H|\theta^i) + \lambda p(\theta^H|\theta^i)}{p(\theta^H|\theta^i) + \lambda p(\theta^H|\theta^i)} \right)}, \\
W_V(\theta^i, V^H) = \frac{\beta \phi}{p(\theta^H|\theta^i) + \lambda p(\theta^H|\theta^i)}. 
\]

(D.29)  
(D.30)  
(D.31)

Consider first the case with \( \theta^i = \theta^H \). Consider \( V'' > V' \), so that from the envelope condition and the strict concavity of \( W(\theta^i, V) \), the associated multipliers satisfy \( \lambda' < \lambda'' < 0 \). Since \( V^{H*}(\theta^H, V) \) is strictly decreasing in \( V \), this means from (D.31) that

$$\frac{\phi''}{p(\theta^H|\theta^i) + \lambda'' p(\theta^H|\theta^i)} > \frac{\phi'}{p(\theta^H|\theta^i) + \lambda' p(\theta^H|\theta^i)}.$$ 

45
Combining this inequality with (D.30) implies that \(s^{H*}(\theta^i, V') > s^{H*}(\theta^i, V')\). From parts (i) and (ii), we know that \(V^{L*}(\theta^i, V'') = V^{L*}(\theta^i, V')\) and \(V^{H*}(\theta^i, V'') < V^{H*}(\theta^i, V')\). Since (25) binds, this implies that \[
\theta^L (U(1 - s^{L*}(\theta^i, V'')) - U(1 - s^{L*}(\theta^i, V'))) + \beta \tilde{s}^L (U(s^{L*}(\theta^i, V'')) - U(s^{L*}(\theta^i, V'))) = \theta^L (U(1 - s^{H*}(\theta^i, V'')) - U(1 - s^{H*}(\theta^i, V'))) + \beta \tilde{s}^L (U(s^{H*}(\theta^i, V'')) - U(s^{H*}(\theta^i, V')))
+ \beta (V^{H*}(\theta^i, V'') - V^{H*}(\theta^i, V'))
< 0.
\]

In order for this inequality to hold, it must be that \(s^{L*}(\theta^i, V'') > s^{L*}(\theta^i, V')\), where we have used the arguments in the proof of part (iv) of Lemma 8 which require \(s^{fb}(\theta^L) > s^{L*}(\theta^i, V) > s^{H*}(\theta^i, V) > s^{fb}(\theta^H) > s^L(\theta^L)\).

Finally, the claim that \(s^{*}(\theta^H, \nabla^H) < s^{*}(\theta^L, \nabla^L)\) follows from analogous arguments to those above, taking into account that the associated value of \(\lambda\) is 0 for \(V = \nabla^i\) for \(i = \{L, H\}\).

D.4 Proof of Proposition 3

**Proof of part (i).** From part (i) of Lemma 2, if \(\eta_t(\theta^{t-1}) = 0\), then \(s_t(\theta^{t-1}, \theta^i) = s^{*}(\theta^L, \nabla^L)\) for \(i = \{L, H\}\). Moreover, if \(\eta_t(\theta^{t-1}) = 1\), then \(s_t(\theta^{t-1}, \theta^i) = s^{*}(\theta^H, V^{H*}(\theta^L, \nabla^L))\) for \(i = \{L, H\}\). Forward iteration implies that if \(\eta_t(\theta^{t-1}) = k\) for \(k > 1\), then \(s_t(\theta^{t-1}, \theta^i) = s^{*}(\theta^H, V^{H*+1}(\theta^H, V^{H*}(\theta^L, \nabla^L)))\), where with some abuse of notation, \(V^{H*+1}(\cdot)\) corresponds to \(k - 1\) iterations of the operator \(V^{H*}(\theta^H, \cdot)\). Therefore, \(\eta_t(\theta^{t-1})\) determines \(s_t(\theta^i)\) conditional on \(\theta_t\).

**Proof of part (ii).** Suppose that \(\theta_t = \theta_{k-1} = \theta^H\), and that \(\eta_k(\theta^{k-1}) = 1\) while \(\eta_k(\theta^{k-1}) = 2\). From part (ii) of Lemma 2, it must be that \(V^t(\theta^{t-1}) < V_k(\theta^{k-1})\). From part (iii) of Lemma 2, this implies that \(s_t(\theta^i) < s_k(\theta^i)\) if \(\theta_t = \theta_k\).

D.5 Proof of Proposition 4

From part (ii) of Lemma 2, \(V^{H*}(\theta^H, V)\) is strictly decreasing in \(V\). We can establish that there exists a unique \(\hat{V}\) with the property that \(V^{H*}(\theta^H, \hat{V}) = \hat{V}\). Note that \(\hat{V}^H > V^{H*}(\theta^H, \nabla^H)\), and it can be shown that \(\hat{V}^H < V^{H*}(\theta^H, \nabla^H)\). To see why, consider the solution to the program given \(V = \nabla^H\), taking into account that this corresponds to the solution to (28) as \(\lambda\) approaches \(-(1 - p(\theta^i|\theta^j))/p(\theta^i|\theta^j)\). The value of the objective for \(\lambda = -(1 - p(\theta^i|\theta^j))/p(\theta^i|\theta^j)\) is weakly exceeded by \[
\theta^H U(1 - s^{fb}(\theta^H)) + \tilde{\theta}^H U(s^{fb}(\theta^H)) + \delta p(\theta^H|\theta^H)W(\theta^H, \nabla^H),
\]
which is the unconstrained value of the objective function uniquely attained under \(s^{H*}(\theta^H, \nabla^H) = s^{fb}(\theta^H)\) and \(V^{H*}(\theta^H, \nabla^H) = \nabla^H\). Note that a solution which satisfies the constraints of the problem and achieves this unconstrained maximum exists. For instance, a potential candidate
solution assigns \( s^H(\theta^H, V^H) = s^L(\theta^H, V^H) = s^{fb}(\theta^H) \) and \( V^H(\theta^H, V^H) = V^L(\theta^H, V^H) = V^H \) and satisfies all the constraints of the problem. Therefore, \( V^H(\theta^H, V^H) = V^H > V^H. \)

Given that \( V^H(\theta^H, V) \) monotonically declines in \( V \), there thus exists a unique \( \hat{V} \) with the property that \( V^H(\theta^L, \hat{V}) = \hat{V} \).

Given that \( V^H(\theta^H, V) \) monotonically declines in \( V \), it follows that if \( V < (>) \hat{V} \), then \( V^H(\theta^L, \hat{V}) > (\leq) \hat{V} \). Therefore, for \( \theta_{t-1} = \theta_t = \theta^H \), if \( V_t(\theta_{t-1}) < (>) \hat{V} \), then \( V_{t+1}(\theta^H) = V^H(\theta^H, V_t(\theta_{t-1})) > (\leq) \hat{V}. \)

\[ \blacksquare \]

E Proofs for Subsection 5.3

E.1 Proof of Lemma 3

From (1) and (5), given (30), we have

\[ \frac{(\tau/(1 - \delta) - b_{t+1})}{T} = \frac{(\tau/(1 - \delta) - b_t)}{T} + \frac{1}{T} \sum_{t=0}^{T} \log(s_t/\delta), \] (E.1)

Taking the log of both sides of (E.1), taking the sum over \( t \) between 0 and \( T \), and dividing by \( T \) yields:

\[ \frac{\log(\tau/(1 - \delta) - b_{T+1})}{T} = \frac{\log(\tau/(1 - \delta) - b_0)}{T} + \frac{1}{T} \sum_{t=0}^{T} \log(s_t/\delta), \]

so that

\[ \lim_{T \to \infty} \frac{\log(\tau/(1 - \delta) - b_{T+1})}{T} = \lim_{T \to \infty} \frac{1}{T} \sum_{t=0}^{T} \log(s_t/\delta). \] (E.2)

If the long run sequence of savings rates is ergodic, the Birkhoff theorem implies that the right hand side of (8) equals \( \bar{\pi} \).\(^{53}\) It therefore follows that if \( \bar{\pi} > 0 \), we obtain from (E.2) that \( \lim_{T \to \infty} \log(\tau/(1 - \delta) - b_{T+1}) = \infty \), which implies \( \lim_{T \to \infty} b_{T+1} = -\infty \). In contrast, if \( \bar{\pi} < 0 \), then analogous reasoning implies that \( \lim_{T \to \infty} \log(\tau/(1 - \delta) - b_{T+1}) = -\infty \) and thus \( \lim_{T \to \infty} b_{T+1} = \tau/(1 - \delta). \)\(^\blacksquare \)

E.2 Proof of Lemma 4

Proof of part (i). Consider the value of \( \bar{\pi}^{fb} \), taking into account that the symmetry of \( p(\theta^i|\theta^i) \) implies that \( \theta^L \) and \( \theta^H \) must occur with equal probability in the long run:

\[ \bar{\pi}^{fb} = \left[ \frac{1}{2} \log \left( \frac{1}{\delta \theta^H + \hat{\theta}^H} \right) + \frac{1}{2} \log \left( \frac{1}{\delta \hat{\theta}^L + \theta^L} \right) \right]. \] (E.3)

Note that
\[
\frac{1}{2} \log \left( \frac{1}{\delta} \tilde{\theta} + \tilde{\theta} \right) + \frac{1}{2} \log \left( \frac{1}{\delta} \tilde{\theta} + \tilde{\theta} \right) = - \left[ \frac{1}{2} \log \left( \frac{\theta + \tilde{\theta}}{\delta} \right) + \frac{1}{2} \log \left( \frac{\theta + \tilde{\theta}}{\gamma} \right) \right]
\]
\[
> - \log \left( \frac{\theta + \tilde{\theta}}{\delta} \right) + \frac{1}{2} \log \left( \frac{\theta + \tilde{\theta}}{\gamma} \right)
\]
\[
\geq - \log \left( \frac{\theta + \tilde{\theta}}{\delta} \right) = 0,
\] (E.4)
where the second inequality follows from Jensen’s inequality and the third inequality follows from algebraic manipulation taking into account that \(\theta_H > \theta_L\). Combined with Lemma 3, \(\pi^f > 0\) implies that assets diverge to infinity in the long run.

**Proof of part (ii).** Consider the value of \(\pi^f\), taking into account that the symmetry of \(p(\theta^i|\theta^i)\) implies that \(\theta^H = \theta^L\) must occur with equal probability in the long run:
\[
\pi^f = \left[ \frac{1}{2} \log \left( \frac{1}{\delta} \tilde{\theta} + \tilde{\theta} \right) + \frac{1}{2} \log \left( \frac{1}{\delta} \tilde{\theta} + \tilde{\theta} \right) \right].
\] (E.5)

Note that
\[
\frac{1}{\delta} \frac{\tilde{\theta}}{\theta^H + \tilde{\theta}} \leq \frac{1}{\delta} \frac{\tilde{\theta}}{\theta^L + \tilde{\theta}} < \frac{1}{\delta} \frac{\tilde{\theta}}{\theta^H + \tilde{\theta}} \leq 1,
\] (E.6)
where we have used (C.8) and the fact that \(\theta_H > \theta_L\). Combined with Lemma 3, \(\pi^f < 0\) implies that debt becomes maximal in the long run. ■

### E.3 Proof of Proposition 5

**Proof of part (i).** If shocks are i.i.d., then (21) implies that \(s_t = \delta\) for all \(t\) under the sequential optimum. This implies that \(\pi^{so} = 0\). Moreover, from (E.1), \(s_t = \delta\) for all \(t\) implies that the level of debt is constant for all \(t\).

**Proof of part (ii).** Consider the value of \(\pi^{so}\) under persistent shocks, taking into account that the symmetry of \(p(\theta^i|\theta^i)\) implies that \(\theta^L = \theta^H\) must occur with equal probability in the long run and taking into account that the savings rates satisfy (21):
\[
\pi^{so} = \left[ \frac{1}{2} \log \left( \frac{1}{\delta} \frac{p(\theta^i|\theta^i)\tilde{\theta}}{\theta^H + \tilde{\theta}} + (1 - p(\theta^i|\theta^i))\tilde{\theta} \right) \right] + \left[ \frac{1}{2} \log \left( \frac{1}{\delta} \frac{(1 - p(\theta^i|\theta^i))\tilde{\theta}}{\theta^H + \tilde{\theta}} + p(\theta^i|\theta^i)\tilde{\theta} \right) \right].
\] (E.7)
Note that by Jensen’s inequality, the right hand side of (E.7) is strictly larger than
\[
- \log \left( \frac{1}{2} \left( \frac{1}{\delta} p(\theta^i|\theta^i)(\theta^H + \tilde{\theta}^H) + (1 - p(\theta^i|\theta^i))(\theta^L + \tilde{\theta}^L) \right) + \frac{1}{\delta} \left( (1 - p(\theta^i|\theta^i))(\theta^H + \tilde{\theta}^H) + p(\theta^i|\theta^i)(\theta^L + \tilde{\theta}^L) \right) \right),
\]
which by algebraic manipulation, taking into account that $\theta^H > \theta^L$, can be shown to be weakly larger than
\[
- \log \left( \frac{\delta \theta^H + \tilde{\theta}^H + \theta^L + \tilde{\theta}^L}{\tilde{\theta}^H + \tilde{\theta}^L} \right) = 0.
\]
Combined withLemma 3, $\bar{s}^{eo} > 0$ implies that assets diverge to infinity in the long run.■

### E.4 Proof of Proposition 6

**Proof of part (i).** This follows directly from Proposition 2 and Proposition 5.

**Proof of part (ii).** Consider $\bar{s}^{eo}$ under persistent shocks in the ex-ante optimum. Recall the the savings rate at any date $t$ is a function only of the current shock $\theta_t$ and the number of periods since the last low shock, $\eta_t$. Moreover, note that given Lemma 2 and Proposition 3, in the long-run ergodic distribution,

\[
\Pr[\eta_t = 0] = \Pr[\eta_{t-1} = 0] p(\theta^i|\theta^i) + \sum_{k=1}^{\infty} \Pr[\eta_{t-1} = k] (1 - p(\theta^i|\theta^i)),
\]

\[
\Pr[\eta_t = 1] = \Pr[\eta_{t-1} = 0] (1 - p(\theta^i|\theta^i)),
\]

\[
\Pr[\eta_t = k] = \Pr[\eta_{t-1} = k - 1] p(\theta^i|\theta^i) \quad \text{for} \quad k > 1.
\]

Since $\Pr[\eta_t = k] = \Pr[\eta_{t-1} = k]$ for all $k \geq 0$ and since $\sum_{k=0}^{\infty} \Pr[\eta_t = k] = 1$, it follows by substituting above that $\Pr[\eta_t = 0] = 1/2$ and $\Pr[\eta_{t-1} = k] = (1 - p(\theta^i|\theta^i)) p(\theta^i|\theta^i)^{k-1}/2$ for $k > 0$. Moreover, conditional on $\eta_t = 0$, the probability of $\theta_t = \theta^L$ is $p(\theta^i|\theta^i)$ and conditional on $\eta_t > 0$, the probability of $\theta_t = \theta^H$ is $p(\theta^i|\theta^i)$. This establishes that $\bar{s}^{eo}$ in equation (32) corresponds to the mean of $\log(s_t/\delta)$ in the invariant distribution of savings rates in the ex-ante optimum.

Finally, to show that both $\bar{s}^{eo} > 0$ and $\bar{s}^{eo} < 0$ may arise for different parameter values, consider the values for $\{\theta^L, \theta^H, p(\theta^i|\theta^i), \delta, \beta\}$ used in Figure 3 (see fn. 47). It is easy to verify using computational methods that if $\beta = 0.01$, then $\bar{s}^{eo} > 0$; by continuity this is also true for a neighborhood of parameter vectors. In this case, Lemma 3 implies that assets diverge to infinity in the long run. Similarly, one can verify that if $\beta = 0.4$, then $\bar{s}^{eo} < 0$, and again by continuity this is true for a neighborhood of parameters. Here Lemma 3 implies that debt becomes maximal in the long run. Lastly, note that in all these cases, parameter values satisfy Assumption 2.■
F Supplementary Appendix for Online Publication Only

This Supplementary Appendix provides proofs for our results in the extension to a continuum of types in Appendix B of the paper.

F.1 Proofs of Proposition 7 and Corollary 2

In order to prove these results, consider the program isomorphic to (16)–(17) under a continuum of shocks. Define a function $h(\theta_t) = \tilde{\theta}_t p(\theta_t | \theta_{t-1})$ for $\theta_t$ which depends on $\theta_t$ as defined in (4). Let $\omega_t = f(\theta_t) \in \Omega \equiv [\omega, \overline{\omega}]$, where it is clear that from Assumption 3, there is a one to one mapping from $\theta_t$ to $\omega_t$. Let $h(\omega_t | \omega_{t-1})$ correspond to the value of $\tilde{\theta}_t p(\theta_t | \theta_{t-1}) (f'(\theta_t))^{-1} / \mathbb{E} [\tilde{\theta}_t p(\theta_t | \theta_{t-1}) | \theta_{t-1}]$, so that $h(\omega_t | \omega_{t-1}) > 0$,

$$h(\omega_t | \omega_{t-1}) d\omega_t = \tilde{\theta}_t p(\theta_t | \theta_{t-1}) / \mathbb{E} [\tilde{\theta}_t p(\theta_t | \theta_{t-1}) | \theta_{t-1}] d\theta_t,$$

and $\int_{\omega} h(\omega_t | \omega_{t-1}) d\omega_t = 1$, where we have used the fact that $d\omega_t = f'(\theta_t) d\theta_t$. Therefore, $h(\omega_t | \omega_{t-1})$ is effectively a density function. Define $H(\omega_t | \omega_{t-1})$ as the associated c.d.f.

Using this formulation, (16)–(17) can be rewritten as

$$\max_{\{s_t(\omega_t)\}_{\omega_t \in \Omega}} \int_{\omega} h(\omega_t | \omega_{t-1})(\omega_t U(1 - s_t(\omega_t)) + U(s_t(\omega_t))) d\omega_t \quad (F.1)$$

s.t.

$$\omega_t U(1 - s_t(\omega_t)) + \beta U(s_t(\omega_t)) \geq \omega_t U(1 - s_t(\omega_t)) + \beta U(s_t(\omega_t)) \quad \forall \omega_t \text{ and } \forall \omega_t \neq \omega_t. \quad (F.2)$$

(F.1)–(F.2) is identical to (16)–(17), where we have used the one to one mapping from $\theta_t$ to $\omega_t$ to write the program as one of choosing a savings rate conditional on the report $\omega_t$.

Now consider a relaxed version of (F.1)–(F.2) which allows (1) to be an inequality:

$$\max_{\{u_t(\omega_t), y_t(\omega_t)\}_{\omega_t \in \Omega}} \int_{\omega} h(\omega_t | \omega_{t-1})(\omega_t u_t(\omega_t) + y_t(\omega_t)) d\omega_t \quad (F.3)$$

s.t.

$$U^{-1}(u_t(\omega_t)) + U^{-1}(y_t(\omega_t)) \leq 1 \quad \forall \omega_t \quad (F.4)$$

$$\omega_t u_t(\omega_t) + \beta y_t(\omega_t) \geq \omega_t u_t(\omega_t) + \beta y_t(\omega_t) \quad \forall \omega_t \text{ and } \forall \omega_t \neq \omega_t. \quad (F.5)$$

(F.3)–(F.5) is identical to (F.1)–(F.2) if the solution admits (F.4) holding with equality $\forall \omega_t$. (F.3)–(F.5) corresponds to the problem analyzed in Section 3.2 of Amador, Werning, and Angeletos (2006) so that their analysis applies here as well.

The envelope condition which characterizes (F.5) implies that

$$\frac{\omega_t}{\beta} u(\omega_t) + y(\omega_t) = \int_{\omega} \frac{1}{\beta} u(\omega') d\omega' + \frac{\omega}{\beta} u(\omega) + y(\omega). \quad (F.6)$$

Standard arguments also require $u(\omega_t)$ to be a non-decreasing function of $\omega_t$. Thus, (F.6) and monotonicity are necessary for incentive compatibility. Substituting (F.6) into the objective function and the resource constraint and integrating by parts allows us to rewrite the problem.
as:

\[
\max_{\{u_t(\omega_t), \bar{y}(\omega)\}} \left\{ \frac{\omega}{\beta} u(\omega) + y(\omega) + \frac{1}{\beta} \int_{\omega}^{\omega'} (1 - G(\omega|\omega_{t-1})) u(\omega_t)d\omega_t \right\} \tag{F.7}
\]

\[
\text{s.t.} \quad U(1 - U^{-1}(u_t(\omega_t)))) + \frac{\omega_t}{\beta} u(\omega_t) - \frac{\omega}{\beta} u(\omega) - \frac{1}{\beta} \int_{\omega}^{\omega'} u(\omega')d\omega' \geq 0 \tag{F.8}
\]

and \(u_t(\omega_t)\) non-decreasing \tag{F.9}

for

\[
G(\omega_t|\omega_{t-1}) = H(\omega_t|\omega_{t-1}) + \omega_t(1 - \beta)h(\omega_t|\omega_{t-1}).
\]

The above program can be solved using Lagrangian methods. Following Amador, Werning, and Angeletos (2006), define \(\omega_p(\omega_{t-1}) = \max\{\omega, \omega'\}\) where \(\omega'\) is the lowest \(\omega \in \Omega\) such that \(\forall \omega'' \geq \omega\),

\[
\int_{\omega''}^{\omega'} (1 - G(\omega''|\omega_{t-1}))d\omega'' \leq 0. \tag{F.10}
\]

Consider the following condition.

**Condition 2.** \(\forall \omega_{t-1} \text{ and } \forall \omega_t \leq \omega_p(\omega_{t-1}), G(\omega_t|\omega_{t-1}) \text{ is non-decreasing in } \omega_t.\)

Proposition 2 in Amador, Werning, and Angeletos (2006) states that the solution to (F.7)–(F.9) admits \(s_t(\omega_t) = s_t(\omega_p(\omega_{t-1}))\) if \(\omega_t \geq \omega_p(\omega_{t-1})\). Moreover, Proposition 3 in that paper states that if Condition 2 holds, then the solution to (F.7)–(F.9) admits (F.8) holding with equality, so that (F.4) also holds with equality. Furthermore, \(s_t(\omega_t) = s^f(\omega_t)\) if \(\omega_t < \omega_p(\omega_{t-1})\), where with some abuse of notation, \(s^f(\omega_t)\) is defined as the flexible optimum given by

\[
\omega_t U'(1 - s^f(\omega_t)) = \beta U'(s^f(\omega_t)).
\]

Let \(s(\omega_{t-1})\) be defined by \(s(\omega_{t-1}) = s^f(\omega_p(\omega_{t-1}))\) if \(\omega_p(\omega_{t-1}) > \omega\), and

\[
\int_{\omega}^{\omega'} h(\omega_t|\omega_{t-1})(\omega_t U'(1 - s(\omega_{t-1})) - U'(s(\omega_{t-1})))d\omega_t = 0
\]

otherwise. \(\forall \omega^f\), it follows then that the sequential optimum features

\[
s_t(\omega^f) = \max\{s^f(\omega_t), s(\omega_{t-1})\}.
\]

This therefore means that the sequentially optimal rule at any date \(t\) can be implemented with a debt limit, which depends only on \(\omega_{t-1}\) and the current level of debt.

In order to complete the argument, we must verify that \(\theta_p(\theta_{t-1}) = f^{-1}(\omega_p(f(\theta_{t-1})))\) and that Assumption 4 is identical to Condition 2. To show that \(\theta_p(\theta_{t-1}) = f^{-1}(\omega_p(f(\theta_{t-1})))\), note that (F.10) can be rewritten as

\[
[1 - H(\omega''|\omega_{t-1})] \omega'' \left( \frac{1}{\beta} - \frac{\int_{\omega}^{\omega'} \omega'' h(\omega''|\omega_{t-1})d\omega''}{\omega''} \right) \geq 0.
\]
Letting $\theta'' = f^{-1}(\omega'')$ and $\theta''' = f^{-1}(\omega''')$ with associated values $\tilde{\theta}''$ and $\tilde{\theta}'''$, the above condition becomes
\[
\left(1 - \frac{\left(f_{\theta''} \theta''' p(\theta'' | \theta_{t-1}) d\theta'' \right) / \left(f_{\theta''} \theta p(\theta'' | \theta_{t-1}) d\theta''ight)}{\theta'' / \tilde{\theta}''} \right) \geq 0,
\]
which becomes (B.1). This establishes that $\theta_p(\theta_{t-1}) = f^{-1}(\omega_p(f(\theta_{t-1})))$.

To show that Assumption 4 is identical to Condition 2, note that $G(\omega_t | \omega_{t-1})$ is continuously differentiable in $\omega_t$ and first order conditions imply that Condition 2 reduces to
\[
\frac{d \log h(\omega_t | \omega_{t-1})}{d \log \omega_t} \geq -\frac{2 - \beta}{1 - \beta}. \tag{F.11}
\]
We can show that (B.2) implies (F.11). Given the definition of $h(\cdot)$, note that the left hand side of (F.11) can be expanded so that (F.11) becomes
\[
\frac{d \log \tilde{\theta}_t}{d \log \theta_t} + \frac{d \log p(\theta_t | \theta_{t-1})}{d \log \theta_t} - \frac{d \log \left(\tilde{\theta}_t / \theta_t \right)}{d \log \theta_t} \geq -\frac{2 - \beta}{1 - \beta},
\]
which is equivalent to (B.2).

### F.2 Proof of Proposition 8

Consider the case of i.i.d. shocks, and with some abuse of notation, let $W_t(\cdot)$ correspond to the continuous type analogue of the continuation value defined in (9) divided by $\delta \mathbb{E}[\theta_t]$, where we have taken into account that shocks are i.i.d. Let the range $[W, \overline{W}]$ correspond to the feasible range of such continuation values. To write the period zero problem, we pursue an analogous strategy as in the proof of Proposition 7 by considering the relaxed problem which allows the resource constraint to hold as an inequality:
\[
\max_{\{u_t(\omega_t), y_t(\omega_t)\}_{\omega_t \in \Omega}} \int_{\Omega} h(\omega_t | \omega_{t-1})(\omega_t u_t(\omega_t) + y_t(\omega_t) + W_t(\omega_t)) d \omega_t \tag{F.12}
\]
\[
\text{s.t. } U^{-1}(u_t(\omega_t)) + U^{-1}(y_t(\omega_t)) \leq 1 \forall \omega_t, \tag{F.13}
\]
\[
\omega_t u_t(\omega_t) + \beta y_t(\omega_t) + \beta W_t(\omega_t) \geq \omega_t u_t(\omega_t) + \beta y_t(\omega_t) + \beta W_t(\omega_t) \forall \omega_t \text{ and } \forall \omega_t \neq \omega, \tag{F.14}
\]
\[
\text{and } W \leq W_t(\omega_t) \leq \overline{W} \forall \omega_t. \tag{F.15}
\]

The same envelope condition in (F.6) applies. Together with the monotonicity of $u_t(\omega_t)$, it implies incentive compatibility. Substituting (F.6) into (F.12), (F.13), and (F.15), the program
can be rewritten as
\[
\max_{\{u(\omega_t),y(\omega)\}, W \leq W(\omega) \leq W} \left\{ \frac{\omega}{\beta} u(\omega) + y(\omega) + W(\omega) + \frac{1}{\beta} \int_{\omega}^{\omega}(1 - G(\omega_t | \omega_{t-1}))u(\omega_t)d\omega_t \right\} \tag{F.16}
\]
\[
\text{s.t.}
U(1 - U^{-1}(u_t(\omega_t))) + \frac{\omega_t}{\beta} u(\omega_t) - \frac{\omega}{\beta} u(\omega) - y(\omega) - W(\omega) - \frac{1}{\beta} \int_{\omega}^{\omega} u(\theta')d\theta' \geq 0 \tag{F.17}
\]
and \(u_t(\omega_t)\) non-decreasing. \tag{F.18}

(F.16)–(F.18) is identical to (F.7)–(F.9) since the term \(y(\omega)\) in (F.7)–(F.9) is replaced with \(y(\omega) + W(\omega)\) in (F.16)–(F.18) and the term \(U(1 - U^{-1}(u_t(\omega_t)))\) is replaced with \(U(1 - U^{-1}(u_t(\omega_t))) + W\). Therefore, the same arguments as those of Amador, Werning, and Angeletos (2006) imply that the solution to (F.16)–(F.18) admits (F.17) holding with equality, which then means that (F.13) holds with equality and \(W(\omega_t) = W\). It thus follows that the solution admits a static mechanism, and therefore the optimal mechanism is characterized as in Proposition 7.\qed

### F.3 Proof of Proposition 9

**Proof of part (i).** Suppose by contradiction that the ex-ante optimum coincides with the sequential optimum, so the solution is characterized by Proposition 7. With some abuse of notation, let \(V^{\theta_0}(\theta_0)\) correspond to the expected date-1 welfare in the sequential optimum to a type \(\theta_0\) who lies and claims to be a type \(\hat{\theta}_0\). By lying, this type receives a mechanism associated with \(\hat{\theta}_0\), evaluated using probabilities \(p(\theta_t | \theta_0)\). Given the description of the solution in Proposition 7, it is straightforward to show that \(V^{\theta_0}(\hat{\theta}_0)\) is continuously differentiable in \(\hat{\theta}_0\) with \(V^{\theta_0}(\theta_0) = 0\) for \(\theta_0 = \theta_0\).

We now consider a perturbation that affects types \(\theta_0 < \theta_p(\theta_{-1})\). To facilitate the construction of the perturbation, note first that one implementation of the sequentially optimal mechanism is as follows. The government can choose any savings rate above \(s^f(\theta_p(\theta_{-1}))\). If the chosen savings rate is \(s_0 > s^f(\theta_p(\theta_{-1}))\), then the mechanism at date 1 corresponds to the sequentially optimal mechanism for type \(s^f(\theta_{-1})\), where \(s^f(\cdot)\) is a function that uses (C.1) to derive the type from the chosen flexible savings rate. If instead the chosen savings rate is \(s_0 = s^f(\theta_p(\theta_{-1}))\), then the government reports its type \(\hat{\theta}_0\), and the mechanism at date 1 corresponds to the sequentially optimal mechanism for type \(\hat{\theta}_0\).

Given this implementation, consider the following perturbation. If the chosen savings rate is \(s_0 = s^f(\theta_p(\theta_{-1}))\), the mechanism is unchanged. If instead the chosen savings rate is \(s_0 > s^f(\theta_p(\theta_{-1}))\), the mechanism at date 1 corresponds to the sequentially optimal mechanism for type \(s^f(\theta_{-1})\), where \(s^f(\cdot)\) is for some continuously differentiable function \(\mu(\cdot)\). Note that if \(\varepsilon = 0\), the original sequentially optimal mechanism is in place. If instead \(\varepsilon > 0\), arbitrarily small, then all types \(\theta_0 \geq \theta_p(\theta_{-1})\) do not change their behavior, but the chosen savings rate \(s_0(\theta_{-1}, \theta_0)\) for types \(\theta_0 < \theta_p(\theta_{-1})\) must satisfy the following first order condition:

\[
-\theta_0U'(1 - s_0(\theta_{-1}, \theta_0)) + \beta \theta_0 U'(s_0(\theta_{-1}, \theta_0)) = -\beta \delta V^{\theta_0}(s^f(\theta_{-1}, \theta_0)) + \varepsilon \mu(s^f(\theta_{-1}, \theta_0)) \frac{ds^f(\theta_{-1}, \theta_0)}{ds_0(\theta_{-1}, \theta_0)}.
\tag{F.19}
\]
As \( \varepsilon \) approaches 0, \( s_0(\theta_{-1}, \theta_0) \) approaches \( s'_0(\theta_0) \). We can show that it must approach it from above; that is, for sufficiently small \( \varepsilon > 0 \), it must be that \( s_0(\theta_{-1}, \theta_0) \geq s'_0(\theta_0) \). If instead \( s_0(\theta_{-1}, \theta_0) < s'_0(\theta_0) \), then type \( \theta_0 \) could make itself strictly better off by increasing its savings rate to \( s'_0(\theta_0) \), as this maximizes its immediate welfare and raises its continuation utility.

Suppose that Condition 1 holds for \( \theta_{-1} \) and some \( \theta_0 \). Together with (F.19), this implies that for a positive measure of types \( \theta_0 \),

\[
[-\theta_0 U'(1 - s'_0(\theta_0)) + \widetilde{\theta}_0 U'(s'_0(\theta_0))] \frac{ds'_0(\theta_{-1}, \theta_0)}{d\varepsilon} \bigg|_{\varepsilon=0} + \delta V^{\theta_0}(\theta_0) \frac{1}{s'_0(\theta_0)} \frac{ds'_0(\theta_{-1}, \theta_0)}{d\varepsilon} \bigg|_{\varepsilon=0} > 0,
\]

where we have used (C.1) and the fact that \( V^{\theta_0}(\theta_0) = 0 \). Therefore, the perturbation strictly increases welfare. Note that if Condition 1 does not hold for \( \theta_{-1} \), then it necessarily holds at some \( \theta_{t-1} \), and the same perturbation can be performed at that date while continuing to satisfy all incentive compatibility constraints at \( t-k \) for \( k > 1 \).

**Proof of part (ii).** Suppose by contradiction that the mechanism does not exhibit history dependence. Let \( V^{\hat{\theta}}(\theta) \) correspond to the continuation value to a type \( \theta \) who reports \( \hat{\theta} \) under this history-independent mechanism, where by assumption, \( V^{\hat{\theta}}(\hat{\theta}) \) is piecewise continuously differentiable. Given that the continuation mechanism is independent of the date, and given that the ex-ante optimal mechanism is chosen at date 0, it follows that \( \forall \theta_{-1} \), the continuation value at date 0 is \( V^{\theta}(\theta) \) if \( \theta = \theta_{-1} \), and by optimality, \( V^{\theta}(\theta) = 0 \). Thus, the first order conditions which guarantee truth-telling whenever the mechanism is differentiable imply that

\[
[-\theta_0 U'(1 - s_t(\theta_{t-1}, \theta_t)) + \widetilde{\theta}_0 U'(s_t(\theta_{t-1}, \theta_t))] \frac{ds_t(\theta_{t-1}, \theta_t)}{d\theta_t} = 0. \quad (F.20)
\]

This requires that either \( s_t(\theta_{t-1}, \theta_t) = s'_t(\theta_t) \) or \( ds_t(\theta_{t-1}, \theta_t)/d\theta_t = 0 \). Therefore, (F.20) effectively corresponds to the first order condition to static incentive compatibility constraints. As such, the optimal mechanism is not dynamic. The solution to the program subject to a sequence of static incentive compatibility constraints coincides with the solution to the sequential optimum described in Proposition 7. However, part (i) shows that this mechanism is suboptimal.
